condition of the gallbladder that radiologically simulates gallbladder carcinoma.⁴⁹ In the few cases in which it is impossible to distinguish complicated cholecystitis from neoplasm, ultrasound-directed or CT-directed needle biopsy can provide a tissue diagnosis. Adenomyomatosis, which is characterized by focal or diffuse gallbladder wall thickening with dilated Rokitansky-Aschoff sinuses, may simulate gallbladder carcinoma on CT. MRI can be useful for distinguishing this entity from gallbladder carcinoma.^{30,31}

The differential diagnosis of those tumors that are manifested as an intraluminal polypoid mass includes adenomatous, hyperplastic, and cholesterol polyps; carcinoid tumor; metastatic melanoma; and hematoma.²⁸ The differential diagnosis for a mass replacing the gallbladder fossa includes hepatocellular carcinoma, cholangiocarcinoma, and metastatic disease to the gallbladder fossa.³⁰ Hepatomas occurring near the gallbladder fossa may be confused with gallbladder cancer radiographically, but they usually occur in cirrhotic livers and do not typically invade the gallbladder. Patients with liver metastases to the gallbladder fossa usually have a known primary neoplasm.

Pathways of Tumor Spread

Gallbladder carcinoma spreads beyond the wall by several routes: direct invasion of the liver, hepatoduodenal ligament, duodenum, or colon; lymphatic spread to regional lymph nodes; hematogenous spread to the liver; intraductal tumor extension; and metastasis to the peritoneum.^{50,51} Distant metastases are unusual.

Gallbladder carcinoma spreads most commonly by direct invasion of the liver.⁵⁰⁻⁵² Liver invasion is facilitated by its proximity and the thin gallbladder wall, which lacks a submucosa and has only a single muscle layer. Invasion of the gastrohepatic

Figure 79-8 Gallbladder carcinoma: MR features. **A.** T2-weighted MR image shows a thickened, moderately hyperintense gallbladder wall (arrows). **B.** T1-weighted MR image demonstrates a thickened hypointense gallbladder wall (arrows). **C.** Postgadolinium fat-suppressed T1-weighted image reveals slightly heterogeneous enhancement of the thickened gallbladder wall (arrows).

Figure 79-9 Gallbladder carcinoma with direct spread to the bile duct. **A** and **B.** Coronal MR images demonstrate an enhancing gallbladder carcinoma with involvement of adjacent bile duct (arrows). **C.** MRCP maximum intensity projection image demonstrates a malignant stricture involving the common hepatic duct as well as narrowing of the lumen at neck portion of the gallbladder (arrow). **D.** Direct cholangiography also demonstrates the stricture (arrow) involving the confluence of the right and left hepatic ducts (hilum of the bile duct), with dilation of the intrahepatic bile ducts.

ligament is also common and may cause biliary obstruction at the porta hepatis. Invasion into the duodenum or colon is less common. On ultrasound images, the gallbladder wall becomes ill-defined as an inhomogeneous mass extends into the liver parenchyma. On CT scans, portions of the invading tumor show enhancement after administration of contrast medium.⁵³ The gallbladder wall is poorly defined adjacent to the carcinoma invading liver parenchyma. Detection of subtle hepatic invasion is improved by use of narrow collimation to avoid partial volume averaging and by coronal or sagittal reformations.⁵⁴ On MRI, direct hepatic invasion and distant liver metastases are well shown on T2-weighted or gadolinium-enhanced images. The tumor has the same signal intensity as the primary tumor in most cases.³⁰

The prevalence of lymphatic spread is high in gallbladder carcinoma⁵⁵ (see Fig. 79-2). Lymphatic metastases progress from the gallbladder fossa through the hepatoduodenal ligament to nodal stations near the head of the pancreas. The cystic and pericholedochal lymph nodes are the most commonly involved at surgery and are a critical pathway to involvement of the celiac, superior mesenteric, and para-aortic lymph nodes.⁵²⁻⁵⁵ Because the gallbladder drains into these more distal nodes, hepatic hilar nodes are usually not involved. Positive lymph nodes are more likely to be greater than 10 mm in anteroposterior diameter and have heterogeneous contrast material enhancement.^{53,54}

Dilated bile ducts are present in about half the patients at the time of presentation.^{28,53,54} Biliary obstruction may develop

in patients with gallbladder cancer for a variety of reasons: lymphadenopathy, usually surrounding the common bile duct; tumor invasion into the hepatoduodenal ligament, often at the porta hepatis (see Fig. 79-9); intraductal tumor growth; or rarely, choledocholithiasis. Adenopathy and invasion into the hepatoduodenal ligament are the most common causes of obstruction; intraductal spread is infrequent but may be seen as a polypoid mass extending into the common bile duct. Ultrasound, CT, and MRI reveal biliary dilation and can usually show the level of obstruction. Invasion of the hepatoduodenal ligament is often better demonstrated with coronal reformatted CT or MRI than with axial CT.⁵⁶⁻⁵⁸

TREATMENT AND PROGNOSIS

Survival in patients with gallbladder carcinoma is strongly influenced by the pathologic stage at presentation.^{16,59} Patients with cancer limited to the gallbladder mucosa have an excellent prognosis, but most patients with gallbladder carcinoma have advanced, unresectable disease at the time of presentation. As a result, less than 15% of all patients with gallbladder carcinoma are alive after 5 years. Surgical management of gallbladder carcinoma is based on the local extension of the tumor. If there is direct extension of disease to the muscularis propria, a radical cholecystectomy is necessary. When disease extends through the serosa, more radical procedures including extended cholecystectomy, pancreatoduodenectomy, and major hepatic resection can be performed. However, radical tumor resection in this

setting is associated with a high operative mortality and few long-term survivors.

Other Malignant Gallbladder Neoplasms

A number of malignant diseases can metastasize to the gallbladder. Among the most common primary malignant neoplasms are melanoma, breast carcinoma, hepatocellular carcinoma, and lymphoma.^{57,60-62} On cross-sectional images, metastases show focal wall thickening, one or more polypoid masses, or replacement of the gallbladder by neoplasm (Fig. 79-10). Metastatic neoplasms of the gallbladder may be indistinguishable from primary gallbladder carcinoma except that gallstones are less frequently seen in patients with metastases.

Primary carcinoid tumors, lymphomas, and sarcomas of the gallbladder have also been reported.^{16,54} Carcinoids and lymphomas are manifested as polypoid masses that sometimes obstruct the cystic duct.⁶³ Sarcomas are bulky polypoid masses that are indistinguishable from primary gallbladder carcinoma.

Benign Gallbladder Neoplasms

A diverse spectrum of benign tumors arise from the gallbladder. Benign neoplasms are derived from the epithelial and non-epithelial structures that compose the normal gallbladder.⁶⁴ Although these lesions are relatively uncommon, their

importance lies in their ability to mimic malignant lesions of the gallbladder. Most benign neoplasms of the gallbladder are adenomas. At gross examination, gallbladder adenomas appear as polypoid structures and may be sessile or pedunculated. They are generally smaller than 2 cm. Tubular adenomas are typically lobular in contour, whereas papillary adenomas have a cauliflower-like appearance.⁶⁴

On ultrasound, adenomas appear as small, broad-based, nonshadowing, sessile or pedunculated polypoid filling defects that do not move with gravitational maneuvers. The echotexture of adenomas is typically homogeneous and hyperechoic. Adenomas tend to be less echogenic and more heterogeneous as they increase in size⁶⁴ (Fig. 79-11). Focal gallbladder wall thickening adjacent to a polypoid mass should raise concern for malignant disease. These polyps are manifested as enhancing intraluminal soft tissue masses. They are difficult to distinguish from the more common cholesterol polyp. Cholesterol polyps are more often smaller and multiple. Other rare benign neoplasms of the gallbladder include cystadenoma, granular cell tumors, hemangioma, lipoma, and leiomyoma.⁶⁴⁻⁶⁶

Cholangiocarcinoma

EPIDEMIOLOGY

Cholangiocarcinoma is a malignant tumor arising from the epithelium of the bile ducts and is the second most common primary hepatobiliary cancer after hepatocellular carcinoma. Cholangiocarcinoma is an uncommon tumor; between 2500

Figure 79-10 Gallbladder metastases. **A.** CT scan obtained during hepatic arterial phase shows an enhancing polypoid mass (arrow) of the gallbladder. Note that left kidney is not shown in the left renal fossa because of previous nephrectomy (star). **B.** Gray-scale ultrasound and color Doppler scans show a polypoid tumor with strong vascular signals (arrow). **C.** Photograph of the opened resected specimen shows a polypoid tumor that was pathologically confirmed as a metastatic renal cell carcinoma (arrow).

Figure 79-11 Gallbladder adenoma. **A.** Sonogram shows a sessile polypoid mass (arrow). **B.** CT scan demonstrates an enhancing polypoid gallbladder adenoma (arrows).

and 3000 new cases of cholangiocarcinoma are diagnosed annually in the United States.^{4,18,19} This tumor is more prevalent in the Far East and Southeast Asia, where liver fluke infection and choledocholithiasis are common. Cholangiocarcinomas occur slightly more often in men, with a male-to-female ratio of 1.3:1; the average age at diagnosis is between 50 and 70 years.⁶⁷ Risk factors for this neoplasm include primary sclerosing cholangitis, choledochal cyst, familial polyposis, congenital hepatic fibrosis, bile duct stone disease, prior biliary-enteric anastomosis, infection with the Chinese liver fluke *Clonorchis sinensis*, and history of exposure to thorium dioxide (Thorotrast).^{68,69}

PATHOLOGIC FINDINGS

More than 95% of cholangiocarcinomas are adenocarcinomas originating from bile duct epithelium. Most cholangiocarcinomas are well to moderately differentiated adenocarcinomas with a tendency to develop desmoplastic reactions and early perineural invasion.⁶⁹ Cholangiocarcinoma is classified anatomically into three groups: intrahepatic and peripheral to the liver hilum, hilar, or extrahepatic. These three types of cholangiocarcinoma are regarded as distinct disease entities therapeutically. Intrahepatic tumors are treated with hepatectomy, when possible, and hilar tumors are managed with resection of the bile duct, preferably with hepatectomy. Extrahepatic tumors are treated in a fashion similar to other periaampullary malignant neoplasms with pancreaticoduodenectomy. Although their precise definitions are controversial, a tumor that arises peripheral to the secondary bifurcation of the left or right hepatic duct is considered an intrahepatic cholangiocarcinoma. A tumor that arises from one of the hepatic ducts or from the bifurcation of the common hepatic duct is classified as a hilar cholangiocarcinoma.⁷⁰ Peripheral intrahepatic cholangiocarcinoma accounts for 10% of all cholangiocarcinomas, hilar cholangiocarcinoma for 25%, and extrahepatic cholangiocarcinoma for 65%.⁷¹

Cholangiocarcinomas are also divided into three types on the basis of their morphology: mass forming; periductal infiltrating, causing stricture; and intraductal growing.⁷¹⁻⁷⁵ This morphologic classification of cholangiocarcinoma is of great importance as it reflects biologic behavior and mode of spread of the tumor, and different types of cholangiocarcinoma may need different staging systems or different treatment strategies.^{73,74} Mass-forming intrahepatic cholangiocarcinoma is a gray-white mass often accompanied by satellite nodules (Fig. 79-12). Fibrosis and necrosis are frequently seen centrally. The

periductal infiltrating type of cholangiocarcinoma grows along the bile duct wall, resulting in concentric mural thickening and proximal dilation.⁷³ A dense fibroblastic reaction may encase the adjacent hepatic artery or portal vein, complicating surgical resection (Fig. 79-13).⁷⁵⁻⁷⁷ Intraductal growing papillary cholangiocarcinoma is characterized by the presence of intraluminal papillary tumors of the intrahepatic or extrahepatic bile ducts with partial obstruction and dilation of the bile ducts (Fig. 79-14).⁷² The tumors are usually small but often spread superficially along the mucosal surface, resulting in multiple tumors along the adjacent segments of the bile ducts or a tumor cast.⁷⁸ Some papillary tumors of the bile ducts produce a large amount of mucin and may impede the flow of bile.^{74,75,78} Ducts both proximal and distal to the tumor can be dilated because mucin may obstruct the papilla of Vater.

CLINICAL FINDINGS

Patients with hilar or extrahepatic cholangiocarcinomas usually present with painless jaundice. Anorexia, weight loss, vague gastrointestinal symptoms, ill-defined upper abdominal discomfort, and elevated serum alkaline phosphatase and bilirubin levels also can be seen. Cholangitis is unusual as a presenting symptom but most commonly develops after biliary manipulation. Patients with intrahepatic cholangiocarcinoma are usually asymptomatic and are rarely jaundiced until late in the course of disease.

RADIOGRAPHIC FINDINGS

The radiologic evaluation of patients with cholangiocarcinoma should delineate the overall extent of the tumor, including involvement of the bile ducts, liver, and portal vessels and distant metastases.¹⁹ Various imaging tests are available to assess patients with cholangiocarcinoma, and the initial radiographic studies consist of either ultrasound or CT. Ultrasound can quickly establish the level of biliary obstruction. Nowadays, MDCT has become the noninvasive diagnostic test of choice for detailed evaluation and staging of cholangiocarcinoma^{76,77} as it is widely available and able to indicate the location of the tumor and show the relationship between adjacent tissues, such as hepatic artery, portal vein, and liver parenchyma. In addition, it also helps survey the entire abdomen for disease staging. In most centers, ERCP or percutaneous transhepatic cholangiography is used to evaluate the extent of biliary involvement and to provide palliation for jaundice.⁷⁶⁻⁷⁸ MRI with MRCP offers the potential of evaluating parenchymal, vascular, biliary, and

Figure 79-12 Intrahepatic mass-forming type of cholangiocarcinoma. **A.** Unenhanced CT shows a low-density mass (arrows) with focal capsular retraction (arrowhead). **B.** Hepatic arterial phase CT shows a nonspecific, malignant-appearing mass with peripheral enhancement (arrows) in the right lobe of the liver. **C.** Portal venous phase scan shows a gradual enhancement of the tumor (arrows) except for central nonenhancing necrotic foci. **D.** Photograph of the resected specimen shows a gray-white mass with capsular retraction (arrow). Fibrosis and central necrosis (arrowhead) are seen in the center.

Figure 79-13 Periductal infiltrating type of cholangiocarcinoma. **A.** Portal venous phase scan shows a luminal narrowing of right intrahepatic bile duct with wall thickening (arrow) with invasion into adjacent hepatic parenchyma and upstream ductal dilation. Note dilation of left intrahepatic bile duct, suggestive of liver fluke (*Clonorchis sinensis*) infestation. **B.** Photograph of the resected specimen of a periductal infiltrating cholangiocarcinoma shows irregular thickening of the right main hepatic duct, with parenchymal invasion (arrow) as well as upstream ductal dilation (open arrow).

Figure 79-14 Intraductal growing papillary cholangiocarcinoma. **A** and **B**. Precontrast and postcontrast CT scans show an intraluminal tumor with papillary projections with weak enhancement (arrow) in the dilated hilar duct. **C**. Axial T2-weighted image shows a papillary cholangiocarcinoma (arrow) in the hilar duct. **D**. Contrast-enhanced axial T1-weighted image demonstrates a heterogeneously enhancing polypoid tumor (arrow) in the dilated common bile duct. **E**. MR cholangiography shows a papillary intraductal mass (arrow) at the hilar portion of the common bile duct with dilation of bilateral intrahepatic duct. **F**. Photograph of the resected specimen shows a large papillary tumor in left hepatic duct and common bile duct (arrow).

nodal involvement with a single noninvasive examination⁷⁷ (see Chapter 80). Although both MDCT and MRI with MRCP showed excellent diagnostic capability for assessing the longitudinal extent and tumor resectability of bile duct cancer, in general, MDCT or MRI generally underestimates the tumor involvement of vessels and lymph nodes.^{79,80} The imaging features of cholangiocarcinoma depend on tumor location and type.

Intrahepatic Type

The most common appearance of a mass-forming cholangiocarcinoma on sonography, CT, and MRI is a well-defined, predominantly homogeneous mass with irregular borders.^{81,82} On sonographic examination, these masses may have mixed echogenicity or may be predominantly hypoechoic or hyperechoic. Because of the peripheral location of the mass, bile duct obstruction is uncommon. Unenhanced CT scans show a hypoattenuating mass, either solitary or with satellite lesions (see Fig. 79-12). After the administration of contrast medium, there is

irregular peripheral and patchy enhancement in the tumor. The dense fibrotic nature of the tumor often produces capsular retraction. Small necrotic regions and focal intrahepatic bile duct dilation around the mass are common.⁸² A higher incidence of cholangiocarcinoma is associated with clonorchiasis (Fig. 79-15). The CT appearance of clonorchiasis is diffuse, mild dilation of the intrahepatic biliary ducts, especially the peripheral portions, without any evidence of obstruction.⁸³ Capsular retraction, dilation of the peripheral bile ducts, and presence of satellite nodules are frequent findings accompanying mass-forming intrahepatic cholangiocarcinoma.⁸²⁻⁸⁵

The typical appearance of cholangiocarcinoma on MRI is a nonencapsulated mass that is hypointense on T1-weighted images and hyperintense on T2-weighted images⁸⁴ (Fig. 79-16). Central hypointensity corresponding to fibrosis may be seen on T2-weighted images. Capsular retraction is found in 21% of mass-forming cholangiocarcinomas and seems to be related to the dense fibrotic nature of the tumor.^{84,86} In addition, in patients with associated clonorchiasis, dilation of the peripheral

portion of the intrahepatic bile ducts is occasionally seen. Cholangiography demonstrates displacement of bile ducts away from the intrahepatic cholangiocarcinoma, obstruction of an intrahepatic duct, or a polypoid mass in the intrahepatic ducts.

Exophytic, intrahepatic cholangiocarcinomas simulate other hepatic malignant neoplasms, particularly hepatocellular carcinoma, on cross-sectional imaging. Most cholangiocarcinomas,

Figure 79-15 Intrahepatic cholangiocarcinoma associated with clonorchiasis. Contrast-enhanced CT scan shows an irregular low-density cholangiocarcinoma (arrows) in the right lobe of the liver and mild, diffuse dilation of intrahepatic bile ducts, suggesting clonorchiasis.

however, occur in noncirrhotic livers. In addition, on dynamic CT or MRI, typical mass-forming cholangiocarcinoma shows thin rimlike or thick bandlike enhancement around the tumor during the hepatic arterial and portal venous phases.^{82,83,87} On delayed (10–15 minutes) scans, there is progressive and concentric filling of the contrast material^{81,86} (see Fig. 79-16). The enhancement pattern of cholangiocarcinoma is explained by slow diffusion of contrast material into the interstitial spaces of the tumor.⁸⁴ This pattern differs from that of hepatocellular carcinoma, which typically shows robust enhancement in the hepatic arterial phase and isoattenuation or low attenuation on the portal venous phase.⁸⁵ A study⁸⁶ reported that hepatobiliary phase imaging of gadoxetic acid-enhanced MRI could improve detection of daughter nodules and intrahepatic metastases compared with dynamic phase images, which might be beneficial for staging and surgical planning of mass-forming cholangiocarcinomas. Hypovascular metastases, especially from adenocarcinoma of the gastrointestinal tract, may show an enhancement pattern similar to that of peripheral cholangiocarcinomas. Absence of a known primary malignant neoplasm, relatively large tumor size, and bile duct dilation favor mass-forming cholangiocarcinomas over metastases.⁸¹

Intrahepatic cholangiocarcinomas may also be polypoid or focally stenotic (Fig. 79-17). If exophytic intrahepatic cholangiocarcinomas are excluded, about three fourths of cholangiocarcinomas are manifested as a focal stricture, and one fourth are polypoid or diffusely stenotic.⁸⁷ Focally stenotic or papillary cholangiocarcinomas often cause segmental bile duct dilation and may induce lobar atrophy if the tumor is central in location. Papillary intrahepatic cholangiocarcinoma occasionally produces abundant mucin, resulting in a well-margined cystic

Figure 79-16 Intrahepatic cholangiocarcinoma.

A. T2-weighted turbo spin-echo image shows a heterogeneously hyperintense cholangiocarcinoma (arrows) in the right lobe of the liver. **B.** Opposed-phase T1-weighted MR image demonstrates a hypointense mass (arrows). **C** and **D.** Dynamic gadolinium-enhanced T1-weighted gradient-echo images at 1 and 5 minutes after injection of contrast material reveal progressive centripetal enhancement of the tumor (arrows).

mass that resembles biliary cystadenocarcinoma (Fig. 79-18). A correct diagnosis of intraductal cholangiocarcinoma can be made by demonstrating direct continuity of the peripheral bile ducts with the tumor and incorporated hepatic parenchyma between cysts.^{88,89} Mucin may result in tumor calcification and can also obstruct the duct lumen distal to the carcinoma (Fig. 79-19).

Hilar Type

Cholangiocarcinomas most often occur at the confluence of the right and left bile ducts and the proximal common hepatic duct.

Figure 79-17 Papillary cholangiocarcinoma. Sonogram shows a papillary cholangiocarcinoma filling the dilated right intrahepatic bile duct (arrow).

These so-called Klatskin's tumors are usually periductal infiltrating types.⁹⁰⁻⁹² The sonographic features of Klatskin's tumors include duct dilation, isolation of the right and left bile duct segments, mass or bile duct wall thickening at the hilum, and lobar atrophy with crowded, dilated bile ducts.^{92,93} Klatskin's tumors almost invariably cause biliary dilation. Although the tumor can appear as mural thickening or an encircling mass along the bile duct wall, a definite mass is rarely seen on ultrasound⁹⁰⁻⁹⁴ (Fig. 79-20). Less often, a polypoid mass can cause hilar obstruction.

CT is more sensitive than ultrasound in detecting obstructing ductal masses, which are usually small (Fig. 79-21). MDCT allows more accurate evaluation of these small lesions and better demonstrates the status of the hepatic arterial or portal venous circulation.⁹² The mass is hypodense to liver on most scans before administration of contrast material.⁸¹ On contrast-enhanced CT, infiltrating tumors are seen as a focal thickening of the duct wall, obliterating the lumen. About 80% of these tumors are hyperattenuating relative to the liver on arterial or portal phase or both (see Fig. 79-13).^{91,92,95} Because of their sclerotic nature, most lesions show delayed tumor enhancement up to 8 to 15 minutes after injection of contrast medium (Fig. 79-22).^{95,96}

Cholangiocarcinomas are either isointense or low in signal intensity relative to the liver on T1-weighted images. On T2-weighted images, the tumor signal intensity ranges from markedly increased to mildly increased relative to liver. Tumors with high fibrous content tend to have lower signal intensity on T2-weighted images⁹⁸ (Fig. 79-23). Cholangiocarcinomas enhance to a moderate degree on gadolinium-enhanced T1-weighted MR images. MRI with MR cholangiography can provide comprehensive evaluation of axial and longitudinal tumor extent of hilar cholangiocarcinomas as well as of vascular

Figure 79-18 Multiple papillary cholangiocarcinomas. **A.** Contrast-enhanced CT shows multiple enhancing papillary cholangiocarcinomas (arrows) in the dilated left intrahepatic bile duct. **B.** Contrast-enhanced CT scan caudal to **A** demonstrates multiple polypoid tumors (arrows) in the dilated common bile duct. **C.** Photograph of the resected specimen shows multiple polypoid tumors in left hepatic duct and common bile duct.

Figure 79-19 Mucin-secreting cholangiocarcinoma. **A.** CT

shows a polypoid mass (arrow) in the left hepatic lobe and dilated left and right intrahepatic bile ducts (curved arrows) and dilated left and common hepatic bile ducts. **B.** ERCP demonstrates mucin expanding the extrahepatic bile ducts (arrows). At endoscopy, mucin was seen coming from the common bile duct.

Figure 79-20 Klatskin's tumor. Sonography of Klatskin's tumor shows dilation of intrahepatic bile ducts and nonunion of right and left intrahepatic bile ducts (arrows).

involvement by the tumors^{77,99,100} (Fig. 79-24). As with CT, contrast enhancement is better appreciated on delayed images because of the nature of the tumor (Fig. 79-25).

Lobar hepatic atrophy with marked dilation and crowding of bile ducts is seen on CT and MRI in approximately one fourth of patients with hilar cholangiocarcinomas.⁹⁴ There is dominant involvement of the duct supplying the atrophied segment. Lobar hepatic atrophy with biliary dilation strongly suggests cholangiocarcinoma, although long-standing biliary obstruction from surgical trauma or focal biliary obstruction can cause similar findings (see Fig. 79-24).^{58,92,100} The liver parenchyma and hepatoduodenal ligaments are commonly invaded by Klatskin's tumors.^{70,90,92,101} Lymphatic metastases most commonly involve the portocaval, superior pancreaticoduodenal, and posterior pancreaticoduodenal lymph nodes.⁵⁴ Retroperitoneal lymphadenopathy, peritoneal spread, and proximal intestinal obstruction occur in advanced stages of hilar cholangiocarcinoma.

Although periductal infiltrating cholangiocarcinoma is the most common type of hilar cholangiocarcinoma, less often,

intraductal growing cholangiocarcinoma can occur in the hilar duct. The intraductal tumors may show higher attenuation than bile on precontrast CT images and hypoenhancement with regard to the hepatic parenchyma on contrast-enhanced images, probably because of lack of fibrotic stroma⁹⁷ (see Fig. 79-14). When intraductal tumors are developed as multiple intraluminal lesions, they can be easily mistaken for intrahepatic duct stones or extrahepatic bile duct stones.^{98,99} Contrast enhancement of the intraluminal lesions on contrast-enhanced CT or MRI can differentiate intraductal growing type cholangiocarcinoma from stones (see Fig. 79-14).^{97,98}

In patients with hilar cholangiocarcinoma, accurate evaluation of tumor extent is necessary for proper treatment and assessment of resectability.¹⁹ Nonresectability of hilar cholangiocarcinoma is suggested by cholangiographic evidence of severe bilateral involvement of the secondary confluence (see Fig. 79-24), involvement of the main trunk of the portal vein, involvement of both branches of the portal vein or bilateral involvement of the hepatic artery and portal vein, or vascular involvement on one side of the liver and extensive bile duct involvement on the other side.¹⁰⁰⁻¹⁰² Unilateral involvement of the hepatic artery or portal vein or both vessels is compatible with resection.^{18,19,100} Precise preoperative evaluation of tumor extent often requires several imaging studies.⁷⁷

Direct cholangiography (Fig. 79-26) is used to evaluate the extent of hilar cholangiocarcinomas.^{77,79} There is characteristic stenosis of the central, right, and left common hepatic ducts, with smooth shoulders or irregular tapering of ducts. These neoplastic strictures tend to branch and may extend into second-order biliary radicles. Direct cholangiography is of limited value in assessing submucosal tumor spread and lesions that extend beyond the porta hepatis because of incomplete filling of bile ducts proximal to the tumor. In addition, CT is ineffective in detecting superficially spreading tumors that extend above the level of biliary obstruction because tumor with a superficial spreading pattern shows enhancement of the inner wall of the bile duct with a preserved lumen.⁷⁰ Therefore, combined assessment with CT and state-of-the-art cholangiography or choledochoscopy (through the percutaneous transhepatic biliary drainage tract) and biopsy are needed to evaluate tumor extent.^{70,81} Along these lines, a combination of MRCP and conventional MRI can provide complete tumor staging

Figure 79-21 Contrast-enhanced CT scans reveal a small enhancing hilar cancers causing biliary strictures (arrow) involving central portion of the left (A) and right (B) bile duct.

Figure 79-22 Hilar cholangiocarcinoma showing delayed hyperenhancement on CT. Contrast-enhanced CT scans during arterial phase (A and B) and delayed phase (C) reveal a homogeneously hyperenhancing, circumferential wall thickening of the hilar duct (arrow) with dilation of both the right and left bile ducts (not shown). Photograph of the resected specimen (D) shows a luminal narrowing and wall thickening (arrows) caused by an infiltrating cholangiocarcinoma involving the proximal common duct as well as bilateral main hepatic ducts.

that assesses liver, portal node, and portal vein involvement^{79,102} (Fig. 79-27).

Hilar cholangiocarcinomas can usually be differentiated cholangiographically from hilar lymphadenopathy or benign stricture. However, differentiating between benign and malignant biliary strictures is sometimes challenging. Indeed, periductal infiltrating type cholangiocarcinomas, especially in the early stage, may be difficult to differentiate from benign strictures.^{80,103,104} Lymphadenopathy compresses and displaces rather than invades the extrahepatic ducts. Benign strictures complicating cholecystectomy or distal gastric surgery are typically short and cause symmetric narrowing of the common hepatic bile duct.¹⁰³ Rarely, lymphoma or sarcoidosis of the bile ducts may be indistinguishable from cholangiocarcinoma.¹⁰² Longer and thicker involvement, luminal irregularity, asymmetric

narrowing, hyperenhancement during portal venous phase, periductal soft tissue lesion, and lymph node enlargement suggest a malignant stricture rather than a benign stricture¹⁰³⁻¹⁰⁵ (see Figs. 79-25 and 79-26). Recently, great attention has focused on immunoglobulin G4 (IgG4)-related sclerosing cholangitis, which can often mimic periductal infiltrating cholangiocarcinoma. Imaging findings such as involvement of intrapancreatic common duct, smooth outer margin, symmetric narrowing of bile ducts, lower degree of dilation of upstream duct, and lower degree of contrast enhancement are more frequent in IgG4-related sclerosing cholangitis than in cholangiocarcinoma^{106,107} (Fig. 79-28). In addition, coexisting autoimmune pancreatitis, good response to steroid therapy, and increase in IgG and IgG4 are helpful clinical and laboratory findings for the diagnosis of IgG4-related sclerosing cholangitis.^{106,107}

Figure 79-23 Hilar cholangiocarcinoma: MR findings. **A.** T2-weighted MR image shows a slightly hyperintense hilar cholangiocarcinoma (arrow). **B.** Fat-suppressed T1-weighted MR image reveals a hypointense hilar cholangiocarcinoma (arrow). **C.** Gadolinium-enhanced T1-weighted image demonstrates an enhancing mass (arrow) in left main hepatic duct. **D.** Photograph of the resected specimen shows an infiltrating cholangiocarcinoma involving the left main hepatic duct and proximal common duct.

Figure 79-24 Comprehensive evaluation of hilar cholangiocarcinoma by MRI with MR cholangiography for surgical resectability. **A and B.** Coronal and axial thick-slab single-shot MR cholangiograms demonstrate hilar cholangiocarcinoma involving both secondary biliary confluences with upstream ductal dilation. Note that segmental intrahepatic ducts of the left lobe are separated by the tumor (arrow). **C and D.** Postcontrast T1-weighted MR images demonstrate a periductal infiltrating hilar cholangiocarcinoma involving ductal bifurcation area and both main hepatic ducts (arrow). The mass (arrow) shows hypoenhancement compared with adjacent liver parenchyma.

Figure 79-25 Delayed contrast enhancement of cholangiocarcinoma: MRI. **A.** Gadolinium-enhanced T1-weighted image obtained during portal venous phase shows an infiltrating hilar cholangiocarcinoma involving ductal bifurcation area and both main hepatic ducts (arrows). **B.** A 10-minute delayed T1-weighted MR image shows delayed enhancement of the mass (arrows). Tumor involves periportal fat with encased left portal vein.

Figure 79-26 Cholangiogram of Klatskin's tumor. Hilar strictures are associated with proximal bile duct dilation.

Extrahepatic Type

Carcinomas of the distal common hepatic or common bile duct are usually small and have a better prognosis than the more central Klatskin's tumor.^{18,19} Fifty percent to 75% of extrahepatic cholangiocarcinomas occur in the upper third, 10% to 30% in the middle third, and 10% to 20% in the lower third of the extrahepatic duct.¹⁰⁸ Cholangiography, either direct cholangiography or MR cholangiography, demonstrates a short stricture or, less often, a polypoid mass, which almost always causes biliary obstruction. CT and MRI can depict an obstructing nodular mass or a concentric or asymmetric thickening of the bile duct wall with enhancement at the transition zone or intraductal polypoid tumors as well as biliary ductal dilation¹⁰⁹ (Fig. 79-29). Adjacent periductal fat may be infiltrated by direct invasion, and lymph node metastasis is relatively frequent. Cholangiocarcinomas that arise in the intrapancreatic portion of the

common bile duct are well depicted as low signal intensity masses against the background of the high signal intensity head of the pancreas on T1-weighted fat-suppressed images and as hyperenhanced thickening of the involved bile duct wall on contrast-enhanced T1-weighted images¹¹⁰ (Fig. 79-30).

For patients with advanced primary sclerosing cholangitis, the risk for development of cholangiocarcinoma is significant. In one study, careful pathologic examination of the native liver removed for transplantation showed that 8% of patients with primary sclerosing cholangitis had coexisting cholangiocarcinoma.¹¹¹ It is often difficult to appreciate malignant degeneration in sclerosing cholangitis. Features that suggest malignancy include progression of strictures on serial cholangiograms, marked biliary dilation above a dominant stricture, and a polypoid ductal mass of 1 cm in diameter or greater¹¹² (Fig. 79-30).

Adults with fusiform extrahepatic choledochal cysts also are at increased risk for development of cholangiocarcinoma (Fig. 79-31). These neoplasms develop within the cyst itself in only about 50% of cases and elsewhere in the biliary system in the remainder. In fact, the cancer can occur after resection of the cyst.¹¹³ Most are manifested as polypoid masses that may be large enough to be visible on cross-sectional imaging.

TREATMENT

Treatment of cholangiocarcinoma includes surgical resection, radiation, laser therapy, biliary stenting, systemic chemotherapy, and liver transplantation.^{18,19,114} There are some long-term survivors after resection, and radiation and bile duct stenting may palliate symptoms for months to years.

Periampullary Carcinoma

Periampullary carcinomas are those tumors arising from or within 1 cm of the papilla of Vater and include ampullary, pancreatic, bile duct, and duodenal cancers.¹¹⁵ It is often impossible by histologic examination to be certain of the origin of the tumor. There is a high incidence of these tumors in patients with familial adenomatous polyposis, and cancer is often preceded by ampullary or duodenal adenomas.¹¹⁵ Periampullary neoplasms tend to be polypoid and lower in grade than more proximal biliary neoplasms.

Figure 79-29 Extrahepatic cholangiocarcinoma. **A.** Axial CT during the portal venous phase shows an enhancing mass (arrow) in common bile duct. **B.** Coronal multiplanar reconstructed (MPR) image demonstrates focal mural thickening and enhancement (arrow) of common bile duct.

Figure 79-30 Cholangiocarcinoma complicating sclerosing cholangitis. Cholangiocarcinoma is causing a stricture (arrows) in the common hepatic duct in a patient with primary sclerosing cholangitis. Despite the dominant stricture with some biliary dilation proximally, this narrowing could be inflammatory or neoplastic. Calculi are present in the right intrahepatic bile ducts.

Biliary dilation to the level of the ampulla of Vater is seen in 75% of cases, and pancreatic ductal dilation is seen in 67%.¹¹⁵ These masses tend to be small and may not be seen on CT scans, in which case abrupt termination of a dilated bile duct in the head of the pancreas is demonstrated, or abrupt termination of the common bile duct without mass may be seen on cholangiography.¹¹⁶ Ampullary cancer can often be manifested as a polypoid mass at the ampulla with dilation of both main pancreatic duct and common bile duct on three-dimensional contrast-enhanced CT or MRI with MRCP¹¹⁶ (Fig. 79-32). On occasion, a villous polypoid lesion may be seen in the distal common bile duct and duodenum. Liver metastasis or lymphadenopathy is

present at the time of diagnosis in only a small percentage of cases.

On T1-weighted fat-suppressed images, periampullary tumors appear as a low signal intensity mass in the region of the ampulla. On immediate postgadolinium T1-weighted images, these lesions are often visualized as areas of low signal intensity, reflecting their hypovascular character compared with background pancreatic tissue.¹¹⁶ On 2-minute postgadolinium fat-suppressed images, a thin rim of enhancement is commonly observed along the periphery of the tumor⁵⁸ (Fig. 79-33). MRCP and sectional MRI can be useful in determining the origins of periampullary carcinomas.

Cystic Bile Duct Neoplasms: Cystadenoma and Cystadenocarcinoma

Biliary cystadenoma and cystadenocarcinoma are rare cystic neoplasms lined by mucin-secreting columnar epithelium.⁶³ On histologic evaluation, they are similar to cystadenomas and cystadenocarcinomas of the ovary and pancreas. They are usually seen in middle-aged women, who present with abdominal pain, distention, and occasionally jaundice. Most cystadenomas and cystadenocarcinomas are manifested as intrahepatic masses that are hypoechoic on ultrasound and have a low-attenuation, uniloculated or multiloculated, cystic appearance on CT.⁶³ The CT attenuation of the fluid component in a biliary cystadenoma depends on the fluid content. Whereas CT is usually superior in demonstrating the size and extent of these tumors, sonography is superior to CT in depicting internal morphology¹¹⁷ (Fig. 79-34). Irregular, papillary growths and mural nodules along the internal septa and wall are seen in cystadenoma and cystadenocarcinoma, although papillary excrescences and solid portions are more common in cystadenocarcinoma¹¹⁷⁻¹¹⁹ (Fig. 79-35). Cystadenomas occasionally have fine septal calcifications; cystadenocarcinomas may have thick, coarse, mural, and septal calcifications.^{117,118} Communication of these tumors with large intrahepatic ducts is rare. Several case reports have suggested malignant transformation of cystadenomas to cystadenocarcinomas on the basis of several years of follow-up after resection.^{120,121} The differential diagnosis of biliary cystadenoma and cystadenocarcinoma includes hepatic cysts, hydatid cysts, liver abscesses, cystic metastases, hematoma, cystic sarcomas, and choledochal cysts.¹¹⁷

Figure 79-31 Cholangiocarcinoma complicating choledochal cyst. **A.** Contrast-enhanced axial CT scan shows a choledochal cyst (arrow). **B.** CT scan caudal to **A** shows an asymmetric thickening (arrow) of intrapancreatic common bile duct with enhancement.

Figure 79-32 Ampulla of Vater cancer. **A.** Axial contrast-enhanced CT scan shows a dilation of the common bile duct and the main pancreatic duct. **B** and **C.** Axial and coronal contrast-enhanced CT scans show a hyperenhancing tumor (arrow) of the ampulla with extension into the main pancreatic duct. **D.** Photograph of the resected specimen shows an irregular mass of the ampulla of Vater (arrows) involving the distal common duct as well as the main pancreatic duct.

Other Malignant Neoplasms of the Bile Ducts

In adults, cholangiocarcinoma and biliary cystadenocarcinoma account for most malignant bile duct neoplasms. Lymphomas, leiomyosarcomas, carcinoid tumors, and metastases rarely occur in the bile ducts (Fig. 79-36). Non-Hodgkin's lymphoma of the bile ducts can rarely mimic cholangiocarcinoma or primary sclerosing cholangitis.^{122,123} In a patient with known lymphoma, cholangiographic findings of smooth, tapered strictures combined with the absence of a portal mass on CT should

suggest the diagnosis. Sarcomas and metastases are manifested as masses projecting into the bile duct lumen, causing biliary obstruction.^{124,125}

After choledochal cyst, embryonal rhabdomyosarcoma is the second most common cause of jaundice in the pediatric population. After infancy, it usually occurs between the ages of 4 and 6 years but has been reported in children aged 1 to 11 years. Sonography and CT will show intrahepatic duct dilation and a soft tissue mass in the region of the common bile duct or porta hepatis. The radiologic appearance of the lesion is similar to that of congenital choledochal cyst if there is no local invasion to adjacent tissues.¹²⁶

Figure 79-33 Ampullary cancer: MR findings. **A.** T1-weighted image shows a hypointense ampullary tumor (arrow). **B.** Postgadolinium fat-suppressed image demonstrates a thin rim of enhancement (arrow) along the periphery of the tumor.

Figure 79-34 Biliary cystadenoma. **A.** CT scan shows a homogeneous, water density mass (arrow) with thin septation in left lobe of the liver. **B.** Septations (arrow) in the cystadenoma are more easily seen on T2-weighted MR image than on CT scan. **C.** Postcontrast T1-weighted MR image shows a mostly nonenhancing mass with thin enhancing septa (arrowheads) in the left hepatic lobe.

Figure 79-35 Biliary cystadenocarcinoma. **A.** Transverse sonogram shows a large, lobulated cystic mass with thick septation and multiple mural nodules (arrows). **B.** CT scan shows a lobulated cystic mass with thick septation and enhancing mural nodules (arrows).

Figure 79-36 Leiomyosarcoma metastatic to the common hepatic duct. **A.** CT scan shows an enhancing polypoid tumor (black arrow) in dilated common bile duct. White arrow indicates a liver metastasis. **B.** Cholangiography shows an intraluminal mass (arrow) of the common bile duct.

Figure 79-37 Multiple bile duct adenomas. **A.** Contrast-enhanced axial CT scan shows an intraluminal polypoid tumor (arrow) with homogeneous enhancement in dilated left intrahepatic bile duct. **B.** CT scan caudal to A demonstrates similar intraductal mass (arrow) in the common bile duct.

Benign Bile Duct Neoplasms

Benign neoplasms of the bile ducts are rare.⁶⁴ Adenomas are the most common type; others include granular cell tumors, hamartomas, fibromas, neuromas, lipomas, and heterotopic gastric or pancreatic mucosal rests.

Most adenomas are manifested as small asymptomatic polyps in the extrahepatic bile ducts that are found incidentally at surgery (Fig. 79-37). On occasion, they become large and cause biliary obstruction. Multiple papillary adenomas have

been reported in association with obstructive biliary villous adenoma and ampullary carcinoma.^{64,127,128} Granular cell tumors of the bile ducts occur most often in young African American women and cause abdominal pain and jaundice.⁶⁵ Most granular cell tumors are extrahepatic masses and are less than 3 cm in greatest dimension, and as the cell infiltrates the wall of the bile duct, the lumen is obliterated. CT and ultrasound usually show bile duct obstruction without identifying the mass. Cholangiography demonstrates either the extrahepatic bile ducts or a small polypoid mass.⁶⁴ Surgical resection is curative.

Echinococcal Cholangitis

Primary Sclerosing Cholangitis

EPIDEMIOLOGY AND CLINICAL FINDINGS

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease of unknown cause. This disease has a typical onset from 20 to 30 years of age but may begin in childhood; it has a 2:1 male-to-female predilection.¹ PSC is commonly associated with inflammatory bowel disease, particularly ulcerative colitis but also, to a much lesser extent, Crohn's disease. Approximately 70% of patients with PSC have ulcerative colitis. In patients with ulcerative colitis, 3% to 7.5% have or will develop PSC.² The term *primary* is used even when there is associated ulcerative colitis because there is no convincing evidence that PSC is caused by or is secondary to inflammatory bowel disease. In fact, the hepatobiliary disease precedes the clinical onset of the bowel disease in some patients. Other associated conditions include sicca complex, Riedel's struma, retroperitoneal fibrosis, and mediastinal fibrosis, but none of these has been reported consistently.^{3,4} Patients with PSC also have an increased risk for cholangiocarcinoma, with a lifetime risk of 10% to 15%.

Approximately 25% of patients with PSC are asymptomatic at presentation.² Clinical features of PSC include fatigue, pruritus, jaundice, right upper quadrant pain, and hepatosplenomegaly. Elevations of serum bilirubin concentration and serum aspartate transaminase activity are usually not as marked or as consistent as increased serum alkaline phosphatase activity. There is strong evidence that genetic and immunologic factors are important in the pathogenesis of PSC. There is no specific serologic marker for PSC.^{5,6} However, approximately 80% of PSC patients have perinuclear antineutrophil cytoplasmic antibodies, also called antimitochondrial antibodies; antinuclear antibodies and anti-smooth muscle antibody are found in 20% to 50% of PSC patients. These markers are nonspecific.

The natural history of PSC is variable but usually progressively downhill, with a 5-year survival of 88% and a median survival of 11.9 years from the time of diagnosis.³ No known therapy, short of liver transplantation, has been proved effective.

PATHOLOGY

PSC is characterized by fibrosing inflammation of the biliary tree (Fig. 80-1). Inflammatory cells are scanty on microscopic examinations, however, and ductal fibrosis is nonspecific and difficult to quantitate pathologically. The diagnosis therefore cannot be made solely on the basis of an extrahepatic duct biopsy specimen.⁷ In fact, biopsy specimens of the extrahepatic ducts should not be obtained unless cholangiocarcinoma must be ruled out.

Tissue samples from the liver may rarely show specific findings of PSC: cholangiectasis in combination with fibrous obliteration of large intrahepatic bile ducts.^{7,8} These tissue samples are generally available only at autopsy or transplantation and not during routine clinical work-up of the patient. Histologic changes found on conventional needle liver biopsy, although not diagnostic, may strongly support the diagnosis of PSC (nonsuppurative, nongranulomatous destruction of septal or interlobular bile ducts in some portal tracts). Other portal tracts in the same patient may demonstrate ductal proliferation and periportal edema secondary to large duct obstruction.⁹ The histologic stages of PSC are as follows: portal hepatitis or cholangitis (stage 1); periportal hepatitis or fibrosis (stage 2); septal fibrosis or bridging necrosis, or both (stage 3); and cirrhosis (stage 4). The injury to the liver in PSC is the result of both a chronic hepatitis and bile duct obstruction, and the staging system applies to the liver disease, not the bile duct lesions.

The term *pericholangitis* has been used when features of stage 1 and stage 2 disease are seen. These changes are now considered to be part of the spectrum of PSC, and patients are classified as having small duct PSC (visible microscopically) or large duct PSC (visible cholangiographically), or both.

Figure 80-1 PSC: pathologic findings. **A.** Cirrhosis from PSC is illustrated here. The liver in PSC typically is green and becomes progressively darker green with advancing stage. **B.** In this advanced case, a peripheral cholangiocarcinoma is present. **C.** Early phases of ductal fibrous cholangitis show concentric periductal fibrosis and mild epithelial atrophy. **D.** Trichrome stain shows dense fibrosis (blue) in this liver.

Large duct PSC virtually always involves the intrahepatic ducts and almost always the extrahepatic ducts. The common bile duct, the common hepatic duct, and the first 1 cm of the left and right hepatic ducts (which are truly anatomically extrahepatic in most patients) are spared cholangiographically in only 1% to 2% of patients. In 20% of patients, the disease is confined cholangiographically to the intrahepatic and hilar ducts.

In the absence of complicating cholangiocarcinoma, large duct PSC progresses slowly. In one series, 80% of patients with uncomplicated PSC showed no change on serial cholangiograms during a period of 6 months to 6.5 years.¹⁰

Gallbladder abnormalities occur in 40% of patients with PSC; the most common abnormality is gallstones (26%). Direct involvement of the gallbladder wall by PSC occurs in about 15% of patients, and approximately 4% of patients have gallbladder neoplasms, such as adenoma and adenocarcinoma.¹¹

RADIOGRAPHIC FINDINGS

Whereas findings from liver biopsy may be compatible with PSC, they alone are not diagnostic. In general, the diagnostic criteria for PSC should include the following: typical radiographic appearance of cholangiographic abnormalities; appropriate clinical, biochemical, and histologic findings obtained from liver biopsy; and exclusion of secondary causes of sclerosing cholangitis. Of these, typical radiographic cholangiographic abnormalities are crucial for the diagnosis of PSC.

FLUOROSCOPIC CHOLANGIOGRAPHY

Although features of PSC can be demonstrated on a variety of imaging modalities, the most important and most

characteristic radiographic findings are seen at fluoroscopic cholangiography¹² (Fig. 80-2). Fluoroscopic cholangiography is usually accomplished by endoscopic retrograde cholangiopancreatography (ERCP). If certain segments of the biliary tract are unable to be visualized by ERCP, percutaneous transhepatic cholangiography may be performed.

Multiple segmental strictures involving both the intrahepatic and extrahepatic bile ducts are the hallmark of PSC. The fluoroscopic cholangiographic findings in PSC depend on the stage of the disease process. Random segments of the biliary tree may be involved by periductal inflammation and fibrosis. In the early phases of PSC, normal or less-involved duct segments may alternate with segmental strictures, producing the classic beaded appearance. Stricture length can vary from 1 to 2 mm (so-called band strictures) to several centimeters; the most common length is 1 to 1.5 cm. Strictures usually occur at the bifurcation of bile ducts and are out of proportion to upstream ductal dilation. When the periductal fibrosis worsens, the bile ducts take on a “pruned tree” appearance that reflects peripheral duct obliteration. In addition, the angles formed with the central ducts become more obtuse.

Diverticular outpouchings, varying in size from 1 to 2 mm to 1 cm, are seen in about 25% of patients on high-quality cholangiograms and are a characteristic feature of PSC. Some diverticula appear to develop as herniations adjacent to strictures, whereas others arise in the absence of strictures, apparently as mucosal extensions into the thickened duct wall.

Almost half of patients with PSC have some degree of mural irregularity varying from a fine, brush-border appearance to a coarse, shaggy, or frankly nodular appearance. The combined findings of short strictures, beading, pruning, diverticula, and mural irregularities often result in a composite cholangiographic appearance that is nearly pathognomonic for PSC.

Figure 80-2 PSC: ERCP findings. **A** and **B.** There are multifocal, irregular strictures and dilations involving the intrahepatic and extrahepatic bile ducts. The strictures are usually short and annular, may appear as webs, and alternate with normal or slightly dilated segments, producing a beaded appearance. Coarse nodular mural irregularities as well as small eccentric outpouchings are often seen.

ULTRASOUND, COMPUTED TOMOGRAPHY, AND MAGNETIC RESONANCE IMAGING

Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) are common first-line imaging tests for abnormal liver function. These modalities can assess for the presence of biliary tract abnormalities. Cross-sectional imaging allows evaluation of not only the bile duct but also the bile duct wall and the surrounding liver parenchyma. In patients with PSC, cross-sectional imaging allows detection of complications such as cirrhosis and malignant disease.

Because ultrasound (Fig. 80-3) is relatively inexpensive and can effectively evaluate the biliary system, it is commonly the initial imaging modality used in the evaluation of cholestatic liver disease. Findings of PSC by ultrasound evaluation include duct dilation and wall thickening of the common bile duct or the intrahepatic ducts in a smooth or irregular manner. The normal intrahepatic bile ducts have a wall thickness of less than 1 mm and appear sonographically as a thin echogenic line. Thickened bile ducts appear as two parallel echogenic lines with a central hypoechoic stripe.¹³ Bile duct wall thickening in PSC usually measures 2 to 5 mm. Common bile duct wall thickening, when it is present, can be easily seen by ultrasound examination. Detection of intrahepatic bile duct wall thickening, on the other hand, is difficult as this modality is operator dependent and this is a subtle finding not always readily apparent.

With ever-improving technology, CT scanning continues to serve as one of the primary imaging modalities for the evaluation of abdominal disease. Current-generation multidetector CT scanners allow rapid acquisition of data and the creation of high-resolution reformatted images for the evaluation of the biliary system, a technique known as CT cholangiography. CT cholangiography uses axial CT data, which are then reconstructed into two-dimensional and three-dimensional images to evaluate the biliary tree, particularly the extrahepatic bile ducts. Oral or intravenous cholangiographic contrast material is used to opacify the bile ducts before scanning. CT cholangiography allows cross-sectional imaging of the biliary tree in patients who do not qualify for MRI, such as patients who have aneurysm clips or a pacemaker, who are claustrophobic, or who

Figure 80-3 PSC: sonographic findings. Mural thickening of the common bile duct (CBD) is identified on this transverse sonogram.

have too many surgical clips within the porta hepatis from prior surgery.¹⁴

CT findings of PSC are similar to ERCP findings and include segmental intrahepatic biliary duct disproportional dilation with focal constrictions (Fig. 80-4). The common hepatic duct and common bile duct can also demonstrate alternating narrowing and dilation. Mural contrast enhancement of the extrahepatic bile ducts can be seen, although this is a nonspecific finding that can be seen with other causes of cholangitis (see Fig. 80-10). Intrahepatic bile duct calculi are present in approximately 8% of patients with PSC. These calculi appear as foci of faint high attenuation or as coarse calcifications and are best seen on non-contrast-enhanced images.¹⁵ Upper abdominal lymphadenopathy is frequently seen in patients with PSC, although this is nonspecific. The presence of lymphadenopathy

Figure 80-4 PSC: CT findings.

A. Irregular intrahepatic bile duct dilation with periductal hyperenhancement is seen. **B.** Abnormal mural thickening and enhancement are identified in the common bile duct. **C.** Non-contrast-enhanced scan shows an intrahepatic bile duct stone (arrow). **D** and **E.** In a different patient, non-contrast-enhanced CT scan shows a nodular liver with marked atrophy of the lateral segment of the left lobe (arrow) and enlargement of the caudate lobe (CL). **F.** Contrast-enhanced scan in a different patient shows cirrhosis of the liver, splenomegaly (S), and adenopathy in the porta hepatis (arrow), a common finding in patients with PSC.

does not necessarily indicate the development of cholangiocarcinoma and should not be regarded as an exclusion criterion for liver transplantation.¹⁶

There are unique hepatic morphologic changes associated with PSC-induced cirrhosis that can be seen with CT. The liver is markedly deformed with severe contour lobulations, creating an organ that appears rounded. This is due to atrophy of both the posterior segment of the right hepatic lobe and the lateral segment of the left lobe and marked hypertrophy of the caudate lobe. In addition, the atrophied right hepatic lobe may be hypodense (due to fibrosis) relative to the hypertrophied caudate lobe, creating the effect of a pseudotumor. When these morphologic changes are seen in conjunction with scattered, dilated intrahepatic bile ducts and intrahepatic bile duct stones, PSC can be suggested as the cause of the cirrhosis.¹⁷ There is substantial overlap in the appearance of livers affected by cirrhosis due to PSC and those affected by end-stage cirrhosis

caused by the usual factors (alcohol and hepatitis). The typical findings of cirrhosis due to any cause include a nodular liver surface from variably sized regenerative nodules, areas of confluent fibrosis, atrophy of the right hepatic lobe, and hypertrophy of the caudate lobe.

Introduced in 1991, magnetic resonance cholangiopancreatography (MRCP) is a technique that uses heavily T2-weighted pulse sequences to depict the bile and pancreatic ducts. MRCP is noninvasive and does not require the use of iodinated contrast material or ionizing radiation.¹⁸ Studies have shown good correlation between MRCP and ERCP in the diagnosis of PSC.¹⁹⁻²² MRCP findings of PSC are similar to ERCP findings and include multifocal segmental strictures alternating with normal or slightly dilated bile duct segments (Fig. 80-5). The strictures are usually out of proportion to the degree of upstream ductal dilation. Periductal inflammation and fibrosis prevent the ducts from dilating; therefore, high-grade strictures can be

Figure 80-5 PSC: MR findings. **A** and **B.** MR cholangiogram shows characteristic irregular strictures and segmental dilations of the intrahepatic and extrahepatic ducts. **C.** Abnormal periductal enhancement is seen after contrast enhancement. **D.** MR image of patient with secondary biliary cirrhosis due to sclerosing cholangitis.

present with only minimal proximal dilation. With progressive fibrosis, the peripheral bile ducts are obliterated, resulting in a pruned tree appearance at MRCP, similar to findings at fluoroscopic cholangiography. Other findings include mural irregularities, webs, diverticula, and stones.²³

Hepatic parenchymal changes associated with PSC can be observed by MRI. Extension of the ductal inflammation into the hepatic parenchyma, retention of bile salts, and accumulation of copper in hepatocytes are thought to be responsible for the parenchymal changes seen on MRI.²⁴ The extrahepatic bile duct demonstrates wall thickening (1.5 mm or more) and enhancement. On T1-weighted images, randomly distributed areas of high signal intensity can be seen in a minority of patients. This abnormal signal is assumed to be due to cholestasis and lipofuscin deposits in atrophic liver cells.²⁵ T2-weighted images may demonstrate increased signal intensity in a peripheral wedge-shaped or fine reticular pattern. Extension of periductal inflammation to involve the vascular and lymphatic channels is considered to be the reason for the signal abnormality. Inflammatory changes of the hilar bile ducts result in a high T2 signal along the porta hepatis.²⁴ Postcontrast images can demonstrate peripheral areas of enhancement possibly due to alterations in blood flow in response to regional inflammation.²⁵

The morphologic changes of the liver affected by cirrhosis from chronic PSC have been previously discussed with respect to CT. These similar changes and others can be observed by MRI. A macronodular pattern of cirrhosis can be demonstrated

in patients with PSC. These large nodules (usually more than 3 cm) can be found predominantly within the central portion of the liver. The nodules are typically isointense on T1-weighted images and hypointense on T2-weighted images. After the administration of contrast material, the nodules are hypointense immediately after the injection and 2 minutes afterward, eventually becoming isointense.²⁶ The peripheral wedge-shaped areas of parenchymal atrophy seen with PSC-induced cirrhosis are typically hypointense on T1-weighted images and hyperintense on T2-weighted images. Corresponding areas demonstrate hypoenhancement on images obtained immediately after administration of contrast material and hyperenhancement on images obtained 2 minutes afterward.²⁶

DIFFERENTIAL DIAGNOSIS

Cholangiocarcinoma

In 90% of cases, cholangiocarcinoma is manifested cholangiographically either as a focal stricture or, less often, as a polypoid mass, neither of which should be confused with PSC. In about 10% of cases, however, there is metastatic spread or multicentricity, or both, such that the tumor involves the biliary tree diffusely and simulates PSC. When diffuse band strictures and multiple diverticula are identified by cholangiography, PSC may be confidently diagnosed because these findings do not occur in cholangiocarcinoma. Only one fourth of patients with PSC demonstrate these findings, leaving a large percentage of PSC patients in whom cholangiocarcinoma cannot be excluded.

Even more of a problem is the fact that cholangiocarcinoma complicates PSC in about 10% to 15% of patients, and when the two diseases coexist, the duct alterations from the underlying PSC can easily mask the presence of the carcinoma.¹⁰ Because of the segmental nature of PSC, some portions of the biliary tree remain relatively free of fibrosis and retain the ability to dilate in response to obstruction. Cholangiocarcinomas usually obstruct more completely than the fibrous strictures of PSC do. Unfortunately, there is no cholangiographic feature that is specific for cholangiocarcinoma. The clinical manifestations of the two diseases are somewhat different; cholangiocarcinoma is more likely when a patient has rapid clinical deterioration of jaundice, pruritus, and weight loss in combination with a rapid rise in serum bilirubin concentration and liver function test results. With regard to cholangiographic findings, more markedly dilated ducts should be viewed as a worrisome sign of complicating carcinoma.

Because PSC is usually a slowly progressive disease, interval stricture formation and biliary dilation on serial cholangiograms favor the presence of superimposed malignant disease, especially in association with clinical deterioration.^{10,27} Intraluminal filling defects occur in 5% to 10% of PSC patients but are usually small, measuring 2 to 5 mm in diameter.

Filling defects of 1 cm or larger occur in about 50% of patients with PSC complicated by cholangiocarcinoma. When they are present, a presumptive diagnosis of malignant disease should be made if choledocholithiasis can be excluded.

On cholangiographic examination, about 25% of patients with PSC show a *dominant stricture*, in which a segment of the biliary tree, often near the hilum, appears more severely strictured than the remainder of the ducts. Although the concept of the dominant stricture was originally proposed to justify aggressive surgical approaches for management of benign strictures of PSC, some dominant strictures actually represent cholangiocarcinomas.²⁸ If cholangiography or clinical course suggests the possibility of complicating cholangiocarcinoma, ultrasound, CT, or MRI should be performed. Cross-sectional imaging can confirm the presence of neoplasm in 50% to 80% of cases,^{29,30} particularly neoplasms arising from intrahepatic ducts, where cholangiocarcinomas often form bulky, exophytic masses. Mural thickening of the extrahepatic bile ducts of 5 mm or more is presumptive evidence of cholangiocarcinoma.³¹ Periportal soft tissue of 1.5 cm or more in thickness is also suggestive of malignant tumor.³² Contrast-enhanced CT and MRI with thin sections and delayed images are superior to 10-mm-thick, unenhanced images and increase the sensitivity for detection of malignant tumors in patients with PSC.

Benign Ductal Diseases

Primary biliary cirrhosis (PBC), secondary sclerosing cholangitis (from a variety of known causes), and some parasitic infestations all share some pathologic, clinical, and imaging features with PSC. The differential diagnostic considerations for these disorders are discussed under their separate headings.

Thiabendazole (Mintezol), an anthelmintic medication, has been reported to cause a cholestatic disorder characterized histologically by destruction of interlobular bile ducts, possibly with an autoimmune basis.³³ Although the microscopic findings can be confused with small duct PSC, the large ducts are normal on cholangiograms, and the history of thiabendazole treatment is diagnostic.

Hepatic sarcoidosis can lead to a granulomatous cholangitis, which on liver biopsy resembles PSC or PBC in some cases.³⁴ In addition, strictures of the extrahepatic bile ducts have been reported in sarcoidosis. The diagnosis is usually known because clinical evidence of sarcoidosis has preceded the onset of cholestasis in reported cases.

Eosinophilic cholangitis is another rare cause of extrahepatic biliary obstruction. Marked wall thickening of the extrahepatic ducts can be seen on CT and sonography.³⁵

Arteriohepatic dysplasia (Alagille's syndrome) is a rare familial cholestatic syndrome characterized by abnormalities of the heart, skeleton, and eyes; characteristic physiognomy including a broad forehead, flattened malar eminence, and pointed mandible; and loss of interlobular bile ducts as seen on liver biopsy.³⁶ Cholangiograms show segmental strictures of both the intrahepatic and extrahepatic bile ducts, resembling PSC. These ductal changes, however, appear to be due to a defect in duct development, leading to segmental hypoplasia or atresia, rather than to be secondary to fibrosis or ductal destruction as found in PSC. The familial inheritance, onset during infancy, absence of associated ulcerative colitis, and characteristic facies should allow easy distinction from PSC (see Chapter 119).

Allograft rejection after liver transplantation can lead to loss of interlobular bile ducts and strictures of the intrahepatic and extrahepatic bile ducts, closely resembling PSC.³⁷ Similar changes in the large bile ducts can result from ischemia if there is a delay in reestablishment of hepatic arterial circulation or if hepatic artery thrombosis occurs after transplantation.³⁷ Other causes of biliary ischemia may also result in biliary strictures resembling PSC.³⁸ In transplantation for PSC, recurrent disease should be considered in patients in whom strictures occur in the absence of rejection, infection, or ischemia. A complete discussion of biliary complications of liver transplantation can be found in Chapter 92.

A spontaneous stricture of the biliary tree, usually a major duct, occasionally causes diagnostic confusion. In most cases, focal biliary strictures have a malignant cause. Some cholangiocarcinomas induce so much fibrosis that biopsy results are falsely negative, leading to an erroneous diagnosis of benign stricture. Nevertheless, benign, focal biliary strictures do occur rarely in the absence of previous surgery, known infection, or other injury. These are sometimes labeled PSC but probably represent a different disease process or at most a *forme fruste* of PSC.

Primary Biliary Cirrhosis

EPIDEMIOLOGY AND CLINICAL FINDINGS

Although the term *primary biliary cirrhosis* was first used in 1950, the condition was originally described nearly 100 years earlier.^{39,40} Similar to PSC, PBC is a chronic cholestatic syndrome of unknown cause characterized by destruction of small bile ducts, portal inflammation, and progressive scarring, with four histologic stages seen on liver biopsy.⁴¹ Chronic cholestasis leads to hepatic copper overload in both PBC and PSC, but the role of copper in duct injury remains unclear (Fig. 80-6).

PBC is the cause of 1% to 2% of deaths from cirrhosis. The disease typically is manifested in middle-aged women with symptoms of fatigue and pruritus and laboratory test evidence of cholestasis. The clinical presentation of PBC is often

Figure 80-6 PBC: pathologic findings. **A** and **B.** Gross appearance of stage 4 disease; a mixture of tan and green regenerative nodules is typical. **C.** Histologic specimen showing periportal inflammation with lymphocytes and plasma cells. **D.** Periductal lymphocytic infiltration is present.

dominated by the insidious onset of diffuse pruritus owing to cutaneous accumulation of bile salts. Itching generally precedes the onset of cutaneous jaundice by 6 months to 2 years. In later stages of the disease, osteomalacia, liver failure, and portal hypertension are seen.

Alterations of cell-based immunity are an important feature of PBC. Sensitized T lymphocytes and possibly B lymphocytes may mediate the duct injury.⁴² PBC is often associated with other autoimmune diseases, and serum antimitochondrial antibody tests are highly sensitive for PBC. Associated autoimmune and collagen-vascular diseases include rheumatoid arthritis, Sjögren's syndrome, Hashimoto's thyroiditis, dermatomyositis, scleroderma, CRST (calcinosis cutis, Raynaud's phenomenon, sclerodactyly, and telangiectasia) syndrome, and systemic lupus erythematosus.

As in PSC, serum alkaline phosphatase activity is reliably increased, whereas serum bilirubin concentration is more likely to fluctuate and is seldom significantly elevated at presentation. Serum bilirubin is an important prognostic indicator; elevated levels are inversely related to life expectancy.

Despite some similarities to patients with PSC, patients with PBC exhibit important differences clinically and pathologically. About 90% of patients with PBC are female; the ratio of males to females in PSC is more than 2:1. Ulcerative colitis is common in PSC but is not associated with PBC. Serologic markers, especially antimitochondrial antibody, are frequently present in PBC, often in high titers, whereas they are not consistently present in PSC. On pathologic examination, small duct destruction in PBC is accompanied by inflammatory cellular infiltrate, including lymphocytes, plasma cells, histiocytes, and eosinophils, and by granuloma formation. In contrast, the destructive cholangitis in PSC is relatively hypocellular and lacks granuloma formation. The conspicuous fibrous thickening of bile duct walls seen in PSC is absent in PBC. The natural history of PBC is variable but usually inexorably downhill; the mean survival in symptomatic patients is 5.5 to 6 years, with a range of 3 to 11 years.⁴³

RADIOGRAPHIC FINDINGS

Imaging typically plays a minor role in the diagnosis of PBC. The diagnosis is usually based on clinical features and laboratory evaluation. Cross-sectional imaging has traditionally been used to stage liver disease by demonstrating portal hypertension and cirrhosis. Imaging is useful to detect the development of hepatic malignant neoplasms.

In most patients with PBC, cholangiograms are normal, especially during the early stages of the disease. With disease progression, the intrahepatic bile ducts can become tortuous and attenuated in response to the surrounding cirrhosis (Fig. 80-7). In areas of parenchymal atrophy, the ducts become crowded and tortuous; in areas of compensatory hypertrophy or nodular regeneration, the ducts become splayed or displaced. There can be extrinsic compression of the common bile duct due to lymphadenopathy within the porta hepatis.⁴⁴

CT and ultrasound scans performed at the time of diagnosis usually demonstrate hepatomegaly (Fig. 80-8). With progression of PBC, the liver volume decreases with atrophy of the right liver lobe and relative hypertrophy of the caudate and left lobes. Several different patterns of fibrosis can be seen in patients with PBC, but the one that seems characteristic is the lacelike pattern of thin or thick bands of low attenuation that surround regenerating nodules. Regenerating nodules are seen as small, rounded, hyperdense foci on unenhanced scans. Fibrosis is best demonstrated on non-contrast-enhanced examinations. Lymphadenopathy is seen in 80% to 90% of patients with PBC and is typically present within the porta hepatis and portacaval locations.⁴⁵ Ascites, splenomegaly, and varices are findings indicative of portal hypertension. These findings can sometimes be observed before clinical and CT findings of cirrhosis develop.

MRI findings are similar to CT scan findings in patients with PBC, demonstrating morphologic changes associated with cirrhosis and lymphadenopathy. An MRI sign that has been described as the "periportal halo sign" can aid in the diagnosis

of end-stage PBC (Fig. 80-9). The periportal halo sign is considered present when a small (5-mm to 1-cm) rounded lesion of decreased T1 and T2 signal intensity is seen surrounding a portal venous branch. Typically, the lesions are numerous, involve all hepatic segments, and fail to exert mass effect.⁴⁶ The

Figure 80-7 PBC: ERCP findings. The intrahepatic bile ducts are small and attenuated, giving the “pruned tree” appearance. The extrahepatic ducts are normal. In PSC, the intrahepatic and extrahepatic ductal systems are usually both involved.

lesions must be differentiated from regenerating nodules, which are usually variable in size and signal intensity and may exhibit mass effect. The sign should also not be confused with periportal edema, which is seen as high signal intensity on T2-weighted images in a periportal distribution. Histologic examination reveals that the periportal halo sign correlates with periportal hepatocellular parenchymal extinction, which is encircled by regenerating nodules.⁴⁶

Cholangiography can be helpful in differentiating PSC from PBC. Strictures are the hallmark of PSC by cholangiography. With PBC, the bile duct deformities are less severe and mainly confined to the intrahepatic bile ducts.¹² The diverticular outpouchings and mural irregularities that are classic in PSC are not seen with PBC.

Obstructive Cholangitis

Biliary obstruction induces bile stasis and predisposes to bacterial infection. Although bacterial cholangitis is nearly always associated with biliary obstruction, benign causes (choledocholithiasis, surgical anastomotic stricture, papillary stenosis) are much more likely to lead to clinical infection than are malignant causes (cholangiocarcinoma, pancreatic carcinoma, malignant hilar lymphadenopathy).⁴⁷

Patients present clinically with right upper quadrant abdominal pain, chills, fever, and jaundice. *Escherichia coli* is the most common infecting organism, but most infections are polymicrobial.⁴⁷ In acute ascending cholangitis, purulent bile may be identified as intraluminal echogenic material within involved ducts by ultrasound or as high-density intraductal material by CT. Cholangiography may demonstrate irregular tubular filling defects in dilated ducts above the obstruction. Hepatic abscesses

Figure 80-8 PBC: CT and ultrasound findings.

A. Transverse nonenhanced CT scan (narrow window setting) shows a small liver with a nodular contour, heterogeneous parenchyma, hypertrophy of the lateral segment, and splenomegaly. Enlarged lymph nodes are present in the porta hepatis. **B.** Contrast-enhanced CT scan of a different patient shows a nodular hepatic contour, hypertrophy of the lateral segment (LS) of the left lobe, and a relatively normal-sized caudate lobe (CL). End-stage PBC is almost always associated with caudate lobe hypertrophy and left lobe atrophy. **C.** Longitudinal scan of the left lobe shows multiple regenerating nodules producing multiple echogenic masses. (Case courtesy Peter Cooperberg, MD, Vancouver, British Columbia, Canada.)

Figure 80-9 PBC: MR features. A to D. Patients with PBC may have a distinctive, conspicuous abnormality of low signal intensity centered around portal venous branches on T1- and T2-weighted MR images, the “periportal halo sign.” This abnormality consists of a rounded lesion centered on a portal venous branch, 5 mm to 1 cm in size. This pattern may involve all hepatic segments and appear as foci of low signal intensity on T1- and T2-weighted images with no mass effect. These criteria allow differentiation of this finding from regenerating nodules, which are usually of various sizes and signal intensity, may exert mass effect, and are not centered on portal venous branches. (Case courtesy Glenn Krinsky, MD, New York, NY.)

not uncommonly complicate the bacterial cholangitis. They are readily demonstrated by ultrasound and CT, and communication with the biliary tree can be documented on fluoroscopic cholangiography (Fig. 80-10).

Although all of the aforementioned are important radiologic signs in obstructive cholangitis, the most important diagnostic objective is to identify the nature and level of the obstruction and to decide the best means of relieving the obstruction. Injection of contrast medium under pressure above an obstruction may exacerbate an existing infection or introduce an infection into a previously sterile biliary tree. If intraductal pressure exceeds portal venous pressure or if communication to the hepatic venous system becomes established, life-threatening septicemia may ensue. Thus, prompt biliary drainage and broad-spectrum antibiotic coverage are mandatory whenever an obstructed infected biliary system is identified on direct cholangiography.⁴⁷

Chronic obstructive cholangitis with repeated episodes of infection may lead to duct strictures, peripheral attenuation of the intrahepatic bile ducts, and biliary cirrhosis. The appearances may resemble PSC, but the cause of obstruction, such as choledocholithiasis or postoperative stricture, is usually clinically or radiologically obvious.

Bacterial infection, usually accompanied by stone formation, may complicate a preexisting biliary tract disease. Congenital cystic disease, including Caroli's disease, is frequently

complicated by choledocholithiasis, infection, and stricture formation, which may potentially mask the underlying disease. Similarly, patients with PSC often form pigment stones within poorly draining portions of the biliary tree, which makes it difficult to establish a primary diagnosis. If clinical and radiologic evidence of an underlying disease is compelling, however, pigmented duct stones and clinical infection should be considered secondary phenomena.^{15,48} Intrahepatic duct stones in PSC patients may be subtle and are often overlooked on contrast-enhanced CT.

Recurrent Pyogenic Cholangitis (Oriental Cholangiohepatitis)

Certain Asian populations have a propensity to form pigmented stones in the intrahepatic and extrahepatic bile ducts that are commonly accompanied by recurrent gram-negative bacterial infections.^{47,49-53} This condition has been variously termed Oriental cholangiohepatitis, Oriental cholangitis, Hong Kong disease, and biliary obstruction of the Chinese. A more inclusive name, recognizing the sporadic occurrence in non-Asians, is recurrent pyogenic cholangitis (RPC). The pattern of stone disease in RPC differs from that in typical Western populations, in which the ductal stones are primarily extrahepatic, are predominantly composed of cholesterol, and most often originate

Figure 80-10 Ascending obstructive cholangitis. **A.** Sagittal sonogram shows a markedly dilated common bile duct (arrows) filled with sludge and stones. **B.** ERCP shows a dilated intrahepatic and extrahepatic biliary system with multiple filling defects (arrow). The patient recovered after urgent papillotomy and administration of antibiotics and intravenous fluids. (From Hanbidge AE, Buckler PM, O'Malley ME, et al: Imaging evaluation for acute pain in the upper abdomen. *RadioGraphics* 24:1117–1135, 2004.)

in the gallbladder.⁵³ Parasitic infestation (*Clonorchis sinensis*, *Ascaris lumbricoides*), malnutrition, and portal bacteremia have been etiologically implicated in RPC, but the cause and pathogenesis remain unproved.

Right upper quadrant pain, chills, fever, and jaundice are the common clinical features of RPC; the natural history is characterized by exacerbations and remissions of cholangitis, with duct injury and cholestasis leading to biliary cirrhosis. During the acute phases, sepsis may be life-threatening.

A suggestive diagnostic finding for RPC is intrahepatic and extrahepatic biliary dilation due to multilevel strictures with associated variable density biliary calculi and sludge.

Figure 80-11 Oriental cholangiohepatitis. Percutaneous transhepatic cholangiography shows severe stricture (arrow), with dilated ducts, multiple filling defects, and abrupt tapering in the right anterior segment. (From Mi-Suk Park M-S, Yu J-S, Kim KW, et al: Recurrent pyogenic cholangitis: Comparison between MR cholangiography and direct cholangiography. *Radiology* 220:677–681, 2001.)

Dilated ducts containing stones and sludge are usually identifiable by CT and ultrasound, although large amounts of nonshadowing, isodense material may mask duct dilation on ultrasound evaluation. All segments of the biliary tree may be involved, but the lateral segment of the left lobe is most often and extensively involved. Additional cross-sectional imaging findings of RPC include parenchymal atrophy, fatty metamorphosis, duct wall enhancement, segmental parenchymal enhancement, hepatic abscess, biloma, and pneumobilia.^{50,51} Strictures are suggested by the presence of abruptly tapered ducts. Cholangiography provides the best detail on the status of the ducts (Fig. 80-11) and is a necessary component of the radiologic interventional management of stones and strictures.^{49,54}

Cholangitis Related to Acquired Immunodeficiency Syndrome

A secondary cholangitis resembling PSC is an uncommon but well-recognized component of acquired immunodeficiency syndrome (AIDS). The condition is thought to be secondary to opportunistic infection by *Cryptosporidium*, cytomegalovirus, or both.⁵⁵⁻⁵⁷ In addition to biliary tract signs and symptoms, patients with AIDS-related cholangitis may have abdominal pain and diarrhea from cryptosporidial enteritis.

Cholangiograms typically show irregularities and strictures of the intrahepatic and extrahepatic bile ducts with associated ductal dilation. Papillary stenosis can occur as an isolated phenomenon or in conjunction with more proximal ductal

Figure 80-12 AIDS-related papillitis. ERCP shows marked dilation of the common bile duct and pancreatic duct, a finding indicating low obstruction.

strictures (Fig. 80-12). Polypoid intraluminal filling defects resulting from granulation tissue have been reported in one fourth of patients on ERCP.⁵⁸ CT and ultrasound may demonstrate mural thickening of the gallbladder and bile ducts as well as other extraductal manifestations of AIDS. A hyperechoic nodule at the distal end of the common duct, attributed to inflammation and edema of the papilla of Vater, has been reported in one series of patients.⁵⁹

Floxuridine Cholangitis

Intra-arterial infusion of chemotherapeutic agents for the treatment of liver metastasis has been shown to cause bile duct strictures.^{38,60-63} In one series, 15% of patients receiving intra-arterial therapy showed abnormalities on cholangiograms in the absence of tumor progression.⁶³ Floxuridine (5-fluorodeoxyuridine) has been the offending agent in almost all cases. Ductal damage is believed to be due to chemical toxic effects of the drug on the ducts or drug-induced intravascular thrombosis of hilar vessels.³⁸ Histologic examination of strictured areas shows dense fibrosis of involved bile ducts and surrounding liver parenchyma. Nevertheless, cholangiograms obtained after cessation of chemotherapy have shown reversibility of some strictures.

In patients with chemotherapy-related cholangitis, direct cholangiography shows segmental strictures of variable length, similar to those seen in PSC. Floxuridine-associated strictures have a marked propensity to involve the hilar area and to spare the lower common duct and the peripheral intrahepatic ducts.⁶³ The gallbladder and cystic duct are also usually more severely involved in floxuridine cholangitis than in PSC. The clinical setting leaves no doubt about the diagnosis if tumor progression can be excluded by CT, MRI, ultrasound, or other means.

Parasitic Infestation

ASCARIASIS

Ascaris lumbricoides is the most prevalent human helminth worldwide (Fig. 80-13). Infestation results from ingestion of ova, with adult worms becoming established in the small bowel after larval migration through the liver and lungs. Clinical symptoms depend on the magnitude of infestation and are generally more frequent and severe in children. The most common clinical presentation is intestinal obstruction secondary to obstruction of the small bowel lumen by a mass of entangled worms. Acute appendicitis and pancreatitis also occur. Biliary colic develops when worms occupy and obstruct the common duct. Surgical removal is curative, but if worms become trapped in the biliary tree and are not removed, thousands of eggs may be released as the worms disintegrate, leading to acute and chronic suppurative cholangitis. In mild cases, ascaridic cholangitis resolves with granuloma formation and scarring. In more severe cases, life-threatening complications may ensue. Extension into the portal or hepatic veins may lead to inflammation and thrombosis (pyelephlebitis). Liver abscesses can potentially perforate into the peritoneal cavity and extend into the pleural space.

Worms may be seen as longitudinal filling defects up to several inches in length on direct or intravenous cholangiograms or as thin, long, or coiled echogenic intraluminal structures on ultrasound scans.^{64,65} The diagnosis of biliary ascariasis is usually made by ultrasound. The roundworms can be observed by ultrasound as intrabiliary tubular structures with echogenic walls and an anechoic line inside. An echogenic focus within a duct can have a “bull’s-eye” appearance.⁶⁶ A central anechoic component, probably representing the worm’s digestive tract, has also been described. Worms may occupy any portion of the biliary tree, including the gallbladder. Real-time ultrasound confirms the diagnosis by demonstrating the worm’s motility.^{66,67} Coexisting intrahepatic and extrahepatic biliary stones may be seen. Uncommonly, roundworms may be found in the liver parenchyma, where they cause secondary hepatic abscesses. This unusual condition is more commonly seen in children with malnutrition.

CLONORCHIASIS

The most clinically important liver fluke is *Clonorchis sinensis*, for which humans are the definitive host (Fig. 80-14). The eggs of *C. sinensis* are passed in human feces, and infestation occurs by ingestion of fish after an initial intermediate phase hosted by one of several types of freshwater snails. Clonorchiasis is endemic in Asia but may be seen in Western countries as a result of travel and immigration.

Within the biliary tree, the worms obstruct the flow of bile and incite an inflammatory cell infiltrate. In later stages, periductal fibrosis, ductal epithelial hyperplasia, and cholangiocarcinoma are seen.⁴⁷ Clinical symptoms depend on the number of flukes, the duration of infestation, and the presence of complications. With mild infections, patients may be asymptomatic. Early symptoms associated with moderate disease are nonspecific and include anorexia, dyspepsia, abdominal fullness, and right upper quadrant discomfort. Severe disease induces more significant systemic symptoms, including palpitations, weight loss, and diarrhea. Jaundice results from obstruction of the

Figure 80-13 Ascariasis. A. Life cycle: Adult worms (1) live in the lumen of the small intestine. A female may produce approximately 200,000 eggs per day, which are passed with the feces (2). Unfertilized eggs may be ingested but are not infective. Fertile eggs embryonate and become infective after 18 days to several weeks (3), depending on the environmental conditions (optimum: moist, warm, shaded soil). After infective eggs are swallowed (4), the larvae hatch (5), invade the intestinal mucosa, and are carried through the portal and then the systemic circulation to the lungs (6). The larvae mature further in the lungs (10 to 14 days), penetrate the alveolar walls, ascend the bronchial tree to the throat, and are swallowed (7). On reaching the small intestine, they develop into adult worms (1). Between 2 and 3 months are required from ingestion of the infective eggs to oviposition by the adult female. Adult worms can live 1 to 2 years. (Source: CDC; available at <http://www.dpd.cdc.gov/>)

C

Figure 80-14 Clonorchiasis. **A.** Life cycle. Embryonated eggs are discharged from the biliary ducts and in the stool (1). Eggs are ingested by a suitable snail intermediate host; there are more than 100 species of snails that can serve as intermediate hosts. Each egg releases miracidia (2_a), which go through several developmental stages [sporocysts (2_b), rediae (2_c), and cercariae (2_d)]. The cercariae are released from the snail, and after a short period of free-swimming time in water, they come in contact and penetrate the flesh of freshwater fish, where they encyst as metacercariae (3). Infection of humans occurs by ingestion of undercooked, salted, pickled, or smoked freshwater fish (4). After ingestion, the metacercariae excyst in the duodenum (5) and ascend the biliary tract through the ampulla of Vater (6). Maturation takes approximately 1 month. The adult flukes (measuring 10 to 25 mm long by 3 to 5 mm wide by 1 mm thick) reside in small and medium-sized biliary ducts. In addition to humans, carnivorous animals can serve as reservoir hosts. (Source: CDC; available at <http://www.dpd.cdc.gov>.) **B.** T-tube cholangiogram shows innumerable 1- to 2-cm filling defects within the dilated bile ducts. The flukes can be identified by their typical comma-shaped or crescentic outlines; other filling defects may represent associated stones and biliary sludge. Short strictures and gross dilations of the ducts are present as the result of chronic obstruction and cholangitis. **C.** Nonenhanced CT scan in the same patient shows hyperdense material within grossly distended major intrahepatic bile ducts that on pathologic examination was proved to be a combination of pigmented biliary stones and sludge and *Clonorchis* flukes. Several calcified stones can be seen in peripheral ducts. The spleen is enlarged. (**B** and **C** courtesy Joan A. Kendall, MD, Honolulu, HI.)

biliary tree by the worms, periductal tissue reaction, or cholangiocarcinoma.

The normal habitat of *C. sinensis* is the intrahepatic bile ducts, where on cholangiograms they appear as ellipsoid, leaf-like filling defects measuring 2 to 10 mm in length.⁶⁸ Contrast opacification of the peripheral intrahepatic ducts is impeded by the worms and periductal tissue reaction.

CT and ultrasound show characteristic dilation of the small intrahepatic ducts with accompanying thickening of the duct wall and periductal tissues. The extrahepatic ducts are typically spared.⁶⁹ Flukes and fluke aggregates are more easily identified within the ducts by ultrasound than by CT. Unenhanced CT scans demonstrate branching low-density structures representing a combination of dilated ducts and periductal inflammatory fibrosis. With contrast enhancement, the apparent diameter of these structures diminishes as the periductal tissue component increases in density and blends in with the surrounding parenchyma.

The association of *C. sinensis* and cholangiocarcinoma is well known.^{68,70} Carcinomas in this setting tend to occur peripherally, where the flukes are most concentrated. Therefore, jaundice is often absent, and the tumors may reach considerable size before detection. Stippled or powder-like areas of high attenuation, corresponding to mucin on pathologic examination, have been reported within cholangiocarcinomas associated with clonorchiasis but not in cholangiocarcinomas without clonorchiasis.⁷⁰ Additional complications of clonorchiasis include

intraductal calculus formation, suppurative cholangitis, cholangiohepatitis, and liver abscess, all of which may yield positive findings on cross-sectional imaging and cholangiography.⁷¹

INFESTATION WITH OTHER LIVER FLUKES

Other liver flukes known to infest humans share many features with *C. sinensis*, including similar life cycles and morphologic features, mode of infestation, and pathologic alterations in the liver and biliary tree with the exception of cholangiocarcinoma. *Opisthorchis felinus* and *Opisthorchis viverrini* gain access to the biliary tree through the ampulla of Vater; *Fasciola hepatica* gains access transperitoneally, by penetrating the liver capsule.^{47,72}

ECHINOCOCCAL CHOLANGITIS

Echinococcus granulosus and *Echinococcus multilocularis* are small tapeworms whose larvae may lodge in human livers.⁴⁷ *E. granulosus* produces hydatid cysts in the liver; *E. multilocularis* produces “alveolar” echinococcosis, a more aggressive, invasive form with much tissue destruction. Either form may compress the biliary tract or rupture into it, producing obstruction, inflammation, and secondary bacterial infection.⁷³ Acute cholangitis may occur when a hepatic hydatid cyst ruptures into the bile ducts. A more complete discussion of hepatobiliary echinococcosis can be found in Chapter 88.

CHAPTER OUTLINE

Laparoscopic Cholecystectomy

Technical Considerations of Laparoscopic Cholecystectomy

Normal Imaging Findings after Uncomplicated Laparoscopic Cholecystectomy

General Postsurgical Complications

Biliary Tract Complications

Biliary-Enteric Anastomosis

Background, Indications, and Technical Considerations
Complications

Post-Traumatic Lesions of the Biliary Tree

Imaging of Post-Traumatic Lesions

The two most common surgical procedures of the biliary tract likely to be encountered in day-to-day practice are laparoscopic cholecystectomy (LC) and biliary-enteric anastomosis. Specifically, given the high prevalence of cholelithiasis or gallstones in the United States, with roughly 20 to 25 million people affected, a large number of patients undergo cholecystectomy each year (~700,000). The revolutionary development and refinement of laparoscopic techniques during the last two decades have allowed LC to largely supplant open surgery.¹⁻³ The creation of a biliary-enteric anastomosis (most often hepaticojejunostomy), on the other hand, can be performed for any number of different indications, the most common of which include liver transplantation, resection of tumors involving the biliary tree, benign or malignant biliary obstruction, biliary stones, and bile duct injuries.^{4,5}

Whereas LC and hepaticojejunostomy are both relatively well tolerated procedures with a low risk of complications, the large number of these procedures performed in the United States each year makes it critical for radiologists to recognize the different complications that may be associated with these surgical procedures and to understand the basic diagnostic and treatment algorithms for each of these complications. This chapter discusses a number of complications associated with LC and hepaticojejunostomy and illustrates their appearances by a number of different radiologic modalities. In addition, this chapter concludes with a discussion of the radiologic diagnosis of post-traumatic lesions of the biliary tree. These traumatic injuries to the bile ducts and gallbladder are relatively rare but can carry a high morbidity and mortality in cases of missed or delayed diagnosis.⁶⁻⁸

Laparoscopic Cholecystectomy

TECHNICAL CONSIDERATIONS OF LAPAROSCOPIC CHOLECYSTECTOMY

The most common indication for LC is symptomatic cholelithiasis, although the procedure is also commonly performed for acalculous cholecystitis, large gallbladder polyps, gallbladder dyskinesia, gallbladder malignant neoplasms, and trauma.⁹⁻¹¹ Contraindications to the procedure are uncommon but typically relate to an inability to tolerate general anesthesia, intractable bleeding disorders, or end-stage liver disease or cirrhosis.^{12,13}

Traditionally, LC has been performed with four incisions (four-port LC; Fig. 81-1A). A 1-cm incision is made adjacent to the umbilicus, and a blunt trocar is inserted into the abdominal cavity, with the subsequent establishment of pneumoperitoneum (10-12 mm Hg) by the insufflation of carbon dioxide through a Veress needle. After the establishment of pneumoperitoneum, a laparoscope is inserted through this first incision. Next, three additional smaller incisions are made in the right lateral upper abdomen and to the left of the falciform ligament, and three trocars are inserted through these sites (Fig. 81-1B). Specialized grasping instruments are then inserted through these trocars to grasp the fundus and infundibulum of the gallbladder, to expose the surgical field, to dissect and clip the cystic artery and duct (with placement of a surgical clip), to remove the gallbladder through the periumbilical port, and to coagulate the gallbladder fossa (Fig. 81-1C, D).^{10,13,14}

Increasingly, however, as a result of patient cosmetic concerns and a desire to reduce operative trauma to the abdominal wall, there has been a trend toward the use of fewer incisions and ports. The newest operative technique, known as single-port laparoscopic surgery, entails the creation of a single periumbilical incision, with the subsequent use of a specialized single port that contains four openings: one for gas insufflation and three for trocars to perform the surgical procedure.¹⁴ Whereas data on these new single-port techniques are still forthcoming, early studies have suggested improved cosmesis and decreased postoperative pain.¹⁴

NORMAL IMAGING FINDINGS AFTER UNCOMPLICATED LAPAROSCOPIC CHOLECYSTECTOMY

In most cases, the imaging findings after LC should be relatively minimal.

- A small amount of pneumoperitoneum is an expected finding.^{15,16} The volume of free air after laparoscopic procedures is generally smaller and lasts for a shorter time compared with open surgery, largely as a result of the relatively small incisions in the anterior abdominal

Figure 81-1 Laparoscopic surgery. **A.** The four trocar insertion sites during laparoscopic cholecystectomy. **B.** Trocars in place during surgery. **C.** Clips are applied to cystic duct. **D.** Gallbladder is prepared for removal.

wall and the use of carbon dioxide for insufflation (which is rapidly absorbed).¹⁷⁻¹⁹ As with other abdominal surgeries, the presence of a large amount of pneumoperitoneum after surgery, or pneumoperitoneum that persists for a longer than expected duration (10-14 days), should raise concern for bowel injury or perforation during the procedure.

- A small amount of subcutaneous emphysema at the incision site is not uncommon, usually resulting from the dissection of insufflated carbon dioxide around the trocars into the subcutaneous soft tissues. This finding is common in the first 24 to 48 hours after surgery but should not be seen in significant amounts thereafter.^{16,20}
- Small densities in the subcutaneous fat surrounding the trocar insertion sites can develop over time and probably represent sites of fat necrosis or scarring related to the surgical intervention.²⁰
- Small postoperative fluid collections in the gallbladder fossa are a common finding immediately after surgery and may be associated with a tiny amount of free fluid in the pelvis.²⁰⁻²³ These fluid collections are almost always asymptomatic and should resolve spontaneously.²¹

Nevertheless, if there are clinical signs of infection, reimaging may be helpful as these collections can rarely become superinfected and develop into abscesses.

- Permanent surgical materials, such as surgical clips, are a common finding in the gallbladder fossa. Potentially confusing, however, is the presence of absorbable hemostatic sponges, occasionally used intraoperatively to control bleeding, which should gradually be absorbed over time. The most commonly used of these materials is gelatin sponge (Gelfoam; Pharmacia and Upjohn, Kalamazoo, Mich) or oxidized absorbable cellulose (Sur-gicel; Ethicon, Somerville, NJ). The appearance of these absorbable agents on computed tomography (CT) is typically as a discrete mass with mixed or low attenuation and with central or peripheral gas collections (Fig. 81-2). In the absence of a reliable clinical history, such an appearance can be extremely difficult to distinguish from a postoperative abscess or fluid collection, and a discussion with the surgeon may be necessary to arrive at the correct diagnosis.²⁴ If not, this absorbable material should disappear in a period of weeks on serial CT examinations.

Figure 81-2 Hemostatic agents (Gelfoam or Surgicel) in gallbladder fossa in three different patients. A to C. CT several days after LC in three different patients shows a low-attenuation, oval, masslike lesion in the gallbladder fossa with focal gas bubbles but no air-fluid level (arrow). This typical appearance of hemostatic agents should not be confused with abscess.

GENERAL POSTSURGICAL COMPLICATIONS

Postsurgical complications after LC are relatively rare. Overall, there is no evidence in the literature that the transition from open to laparoscopic surgical technique has resulted in any appreciable increases in morbidity or mortality. A Cochrane Database review that examined 38 different studies in the literature (with 2338 patients) found no difference in mortality between open cholecystectomy and LC, and although there was the suggestion of a lower overall complication rate with laparoscopic technique, this could not be validated in the highest quality studies. Moreover, laparoscopic technique is clearly associated with a shorter hospital stay, better cosmetic results, less postoperative pain, and faster return to work.^{13,25}

Nevertheless, postsurgical complications are not infrequently encountered regardless of the surgical technique used. Complications are thought to be more likely in patients with active (or prior bouts of) cholecystitis, longer time (typically > 72 hours) between the onset of cholecystitis symptoms and surgery, male gender, prior upper abdominal surgery, significant pericholecystic fluid, high body mass index, diabetes, and advanced age, all of which are factors that may render LC more technically difficult.^{9,13,26,27} Notably, these same patient factors represent the most common risk factors for conversion of LC into an open procedure, and the conversion rate is thought to be as high as 12%.^{3,28,29} As one would expect, patients with significant gallbladder inflammation (including gangrenous and emphysematous cholecystitis) are also at higher risk for complications and conversion to an open procedure.³⁰

Complications of LC include those associated with the laparoscopic component of the procedure as well as those related to the cholecystectomy itself.¹⁰ The most common complications related to laparoscopy include abdominal wall or omental bleeding, intraperitoneal or retroperitoneal vessel injury, bowel

injury or perforation, and solid visceral organ injury. The most common complications related to cholecystectomy include gallbladder fossa bleeding, bile duct injury, bile leakage, gallbladder perforation (with stone spillage), retained biliary stones, and biliary strictures.¹⁰ Less commonly, laparoscopic cholecystectomies can be complicated by vascular injuries, with an incidence ranging between 0.05% and 0.25%. Vascular injury is the second leading cause of death in patients undergoing laparoscopic procedures (of any kind), and the hepatic artery is the most frequently injured vessel during LC. Given that the mortality rate for patients suffering vascular injuries during laparoscopy can be as high as 9%, careful evaluation of the hepatic artery along its entire course is critically important in evaluating multidetector CT (MDCT) studies in patients who have recently undergone LC.³¹

The majority of complications are manifested in the early postoperative period, but others may appear weeks or even months after the procedure.^{10,21,32} Most patients undergoing LC experience an uneventful, straightforward postoperative course, but a high index of suspicion is essential for those patients who demonstrate any concerning symptoms, including fevers, persistent abdominal pain, tachycardia, vomiting, or high degrees of bile output from a drain or wound site.

BILIARY TRACT COMPLICATIONS

Biliary tract complications are the most important complications of cholecystectomy and represent a major source of litigation.³³ Biliary tract complications can be encountered with both open and laparoscopic cholecystectomies, and there is little evidence of any increase in biliary tract complications with laparoscopic technique. Many of these complications are often not recognized at the time of surgery and are not uncommonly diagnosed after a significant delay, resulting in considerable

patient morbidity and mortality.^{26,27,33,34} The most important biliary complications for the radiologist to recognize are bile duct injury, bile leak, retained stones, bile duct strictures, and spilled stones in the peritoneal cavity.²¹

Bile Duct Injury and Bile Leak

There are more than 2500 bile duct injuries related to LC in the United States each year, and many of these injuries are attributable to acute or chronic inflammation obscuring fat planes surrounding the gallbladder or intraoperative misidentification of the common bile duct (CBD) by the surgeon.³⁵ Other risk factors include inadequate exposure, patient obesity, congenital anatomic anomalies of the bile ducts, emergent surgery, and failed cholangiography.³⁶⁻³⁸ The incidence of bile duct injury after LC is 0.1% to 1.3%, and although there does not appear to be a significant difference in the incidence of bile duct injuries compared with open procedures, injuries after LC may possibly be more severe.^{13,26,33,37,39-47}

Bile duct injuries encompass a wide range of different lesions, including tears, transections, and ligations.⁴⁸ The most common injury results in a defect of the CBD due to a portion of the CBD having been mistaken for the cystic duct and, as a result, being partially or completely transected.⁴⁶ Many minor bile duct injuries (perhaps seen in up to 1.2% of patients) are now successfully treated with endoscopic management (usually internal drainage), allowing bile flow away from the site of injury into the duodenum and consequently allowing the injured bile duct segment to heal. On the other hand, complex or severe bile duct injuries (i.e., common hepatic duct, CBD, right hepatic duct, or transection of the right posterior sectoral duct) are almost always treated with surgical biliary reconstruction.^{37,49}

There is debate within the surgical literature as to whether the routine use of intraoperative cholangiography (IOC) can help reduce the incidence of bile duct injury, and some surgeons

advocate that cholangiography should constitute a routine component of every LC. Proponents argue that IOC can help better define biliary anatomy, thereby reducing the incidence of biliary injuries. Moreover, in those cases in which injuries occur, proponents argue that IOC allows earlier discovery of these injuries.⁵⁰ However, those who argue against routine cholangiography suggest that instead of reducing the incidence of bile duct injury, surgeons performing IOC may actually cause a bile duct injury while attempting to cannulate the cystic duct or by inadvertently cannulating the CBD.⁵¹ Moreover, IOC undoubtedly increases operative time and surgical costs.^{44,47}

Depending on its severity, bile duct injury can result in a frank bile leak (Figs. 81-3 to 81-9). Whereas bile leaks can theoretically occur at any site of bile duct injury, the most common locations are the cystic duct stump, the duct of Luschka, and the gallbladder bed.³⁹ When leaks occur at the cystic duct stump (the most common site of bile leak), causes can include a misplaced surgical clip, resulting in inadequate closure of the cystic duct; necrosis of the cystic duct after placement of a clip; elevated CBD pressures (often due to a distally impacted CBD stone) transmitted to the cystic duct, resulting in cystic duct "blow-out"; and operative injury to the cystic duct.^{46,52} In those cases attributable to operative injury, leaks may occur because of difficulty in dissecting the cystic duct and common hepatic duct, particularly when adhesions are present, and as a result of unrecognized aberrant ducts.^{20,46} The second most common site of bile leak is from the duct of Luschka, an accessory duct in the right hepatic lobe that traverses the gallbladder fossa and can drain into either the right or common hepatic duct. This bile duct is uniquely vulnerable to injury and leak as a result of its variable course and location within the operative field.³⁹

Bile leaks carry a high risk of morbidity and mortality and should be suspected in any patient who presents with fever, jaundice, abdominal pain, peritonitis, or elevated liver function test results in the first week after surgery.^{39,53,54} In particular, a

Figure 81-3 Bile leakage resulting in a biloma, biliary ascites, and peritonitis. **A.** CT 6 days after LC shows an oval fluid collection, a biloma, in the gallbladder fossa (arrow) adjacent to a surgical clip (arrowhead). The leaking bile assumes a pear-shaped configuration resembling the gallbladder. There is some free fluid in Morison's pouch. **B.** Inflammatory changes induced by leaking bile seen as marked omental infiltration (arrow), displacing the ascending colon medially. **C.** Large amount of fluid in pelvis (arrows); its clear density, although nonspecific, is compatible with bile. **D.** Subsequent ERCP shows active extravasation of contrast material, probably from the cystic duct remnant (arrow).

Figure 81-4 Bile leakage inducing bile peritonitis **A.** Ten days after LC, CT shows free fluid, compatible with bile, around the spleen and the liver. **B.** Pelvic CT shows a large amount of free fluid and marked infiltration of the mesentery and omentum, indicating infected bile.

Figure 81-5 Bile leak confirmed by hepatobiliary scintigraphy and ERCP. **A.** CT on sixth postoperative day after LC shows minimal fat infiltration near gallbladder bed (arrow) and a small amount of free fluid around the liver. **B.** Inflammatory changes in the omentum in right midabdomen (arrow). **C.** Small to moderate amount of clear free fluid in pelvis (arrow). Its clear density, although nonspecific, is compatible with bile. **D.** Hepatobiliary scintigraphy shows active extravasation of radiotracer in the gallbladder fossa (arrow). **E.** Subsequent ERCP shows active extravasation of contrast material from the cystic duct stump (arrow).

Figure 81-6 Bile leak confirmed by ERCP. **A.** CT obtained 5 days after LC shows free fluid in the upper abdomen mainly around the spleen and the liver and some fluid also in the gallbladder fossa, adjacent to a surgical clip. **B.** ERCP after the CT study shows extensive extravasation, probably from the cystic duct remnant (arrows).

Figure 81-7 Bile leak confirmed by hepatobiliary scintigraphy. **A.** CT on second postoperative day after LC in 63-year-old woman with leukocytosis shows minute amount of free fluid around liver (long arrow) and in gallbladder fossa (short arrow); however, a large amount of clear fluid is seen in the pelvis (**B**). **C.** ^{99m}Tc -labeled iminodiacetic acid (HIDA) by single photon emission computed tomography (SPECT) on twelfth postoperative day shows active extravasation of radiotracer in the gallbladder fossa (short arrow) and biliary ascites around liver and in right paracolic gutter (long arrow).

markedly elevated serum bilirubin level and, alternatively, the presence of significant bile output from an abdominal drain are both features highly suggestive of a large biloma, although the absence of bile output from an abdominal drain cannot exclude a bile leak.³³ Bile can leak freely into the peritoneal cavity, resulting in either sterile or infected biliary ascites (see Figs. 81-3 to 81-7 and 81-9), or accumulate into a loculated fluid collection, resulting in a sterile biloma (see Figs. 81-3A and 81-8) or an infected abscess (Fig. 81-10).^{38,55}

The treatment of bile duct injuries and leaks remains controversial, and there are a number of different management algorithms in use. In general, patients with a suspected bile leak and a single fluid collection or biloma on CT are initially treated with placement of a percutaneous drainage catheter. Although it is uncommon, in a small subset of patients with a minor leak and minimal bile duct injury, there is the possibility of spontaneous resolution of the leak after placement of the drainage catheter. If the leak then fails to resolve, patients typically

proceed to endoscopic retrograde cholangiopancreatography (ERCP), in which minor leaks are treated with placement of a biliary stent. The biliary stent diverts bile away from the site of biliary injury into the duodenum, giving the injured segment time to heal (see Fig. 81-9B). Notably, whereas sphincterotomy has traditionally been thought to be useful in these patients, there is now little consensus in the literature on its utility; some studies suggest that this procedure raises the risk of perforation, bleeding, and mortality, and there are few data to suggest that sphincterotomy provides benefit in terms of leak resolution.³⁴ If a major bile leak or significant biliary injury is detected on ERCP, patients undergo operative repair and biliary reconstruction.^{37,56,57}

Figure 81-8 Bile leak from cystic duct stump. Endoscopic retrograde cholangiography 9 days after LC shows leak of contrast material originating adjacent to surgical clips (arrowhead) at the cystic duct stump. The leaking contrast material assumes a pear-shaped configuration, a biloma, resembling the gallbladder (arrows).

Figure 81-9 Bile leak after cholecystectomy. A and B. ERC 10 days after cholecystectomy (for gallbladder cancer) shows active extravasation of contrast material (arrows). This was considered a “minor” leak and treated with ERCP-guided stent placement (arrowheads in B).

Retained Biliary Stones

Small biliary stones occasionally remain after LC, often within the intrahepatic or extrahepatic biliary tract.⁹ Moreover, in some cases in which LC is technically challenging as a result of difficulty in identifying anatomic landmarks, adhesions, marked bleeding, or severe gallbladder inflammation, portions of the gallbladder infundibulum may be inadvertently left behind (subtotal cholecystectomy), and this gallbladder remnant may contain stones.^{41,58} Such incomplete resection of the gallbladder is relatively common, occurring in up to 13.3% of cholecystectomies.⁵⁹ For the same reasons, particularly in patients with an unusually long cystic duct, portions of the cystic duct containing stones may also be left behind after surgery.⁵⁸

These retained stones, regardless of whether they reside within the intrahepatic biliary tree, CBD, cystic duct stump, or gallbladder remnant, may subsequently migrate distally into the CBD, resulting in biliary obstruction (Fig. 81-11). The overall incidence of retained stones, regardless of location, after LC is 0.5%; the most common location for retained stones is within the CBD, with an incidence ranging between 5% and 15%.⁶⁰⁻⁶⁵ There is some debate in the literature as to the necessity of defining the presence of biliary tract stones (outside the gallbladder) by preoperative magnetic resonance cholangiopancreatography (MRCP), and some surgeons advocate performing intraoperative cholangiography for the purpose of detecting biliary stones in the highest risk patients during cholecystectomy.^{65,66}

It is thought that retained stones in the biliary system after cholecystectomy may be a common cause for postcholecystectomy syndrome, a term used to describe the recurrent biliary colic symptoms suffered by 10% to 40% of patients after cholecystectomy.^{41,58} Symptoms of retained biliary stones can include jaundice and right upper quadrant pain, and the diagnosis is usually made in the first 2 months postoperatively.^{27,44} Rarely, retained distally impacted stones in the CBD may secondarily result in biliary leakage from the cystic duct remnant by causing increased biliary pressure that displaces the cystic duct clips, a phenomenon often referred to as cystic duct blow-out.⁹ Retained stones can usually be extracted by ERCP and sphincterotomy. Open or laparoscopic CBD exploration is only rarely necessary.^{27,44}

Figure 81-10 Postoperative abscess after LC. **A.** Contrast-enhanced CT shows gas-containing abscess anterior to liver (A). Fluid and gas in gallbladder fossa (short arrow). Fluid around liver (long arrow). **B.** Coronal reformat shows full extent of abscess cavity (A). **C.** Coronal reformat shows fluid in gallbladder fossa (straight arrow) and pelvis (curved arrow).

Bile Duct Strictures

Postoperative biliary strictures are not uncommon with both open and laparoscopic cholecystectomies. Several different causes have been proposed, including focal bile duct ischemia due to intraoperative damage and thermal injury during surgical dissection, intense connective tissue response with fibrosis and scarring as a result of bile duct manipulation, inadvertent clipping or ligation of the bile duct, and scarring as a result of T-tube placement (Figs. 81-12 and 81-13).^{38,54,59,67}

Biliary stricture after cholecystectomy is relatively rare, occurring in 0.2% to 0.5% of patients. In many cases, these strictures are not recognized for months or years after the patient's surgery, with a mean time to stricture of 3 to 6 months.⁶⁷ Many patients are not overtly symptomatic, and the

diagnosis is often made on the basis of progressive biliary dilation on cross-sectional imaging. In other cases, patients can present with painless jaundice, cholangitis, or sepsis. Patients with a markedly delayed diagnosis may ultimately present with advanced biliary cirrhosis and its complications.³⁸

Whereas surgical treatment (usually in the form of a Roux-en-Y hepaticojejunostomy) has traditionally been the treatment of choice for iatrogenic biliary strictures related to LC, endoscopic treatment is increasingly becoming the first-line treatment of choice.^{54,68} In addition to being safer and better tolerated (with lesser degrees of associated morbidity and mortality), endoscopic balloon dilation with stent placement has been associated with a lesser risk of recurrent strictures and cholangitis, although patients may require multiple sessions of balloon dilation with periodic replacement of bile duct stents.⁶⁹ In

particular, endoscopic approaches appear to be more effective for strictures in the distal CBD, whereas surgery may still be the preferred option for complex strictures in the more proximal CBD.⁶⁷

Imaging of Postoperative Bile Duct Injuries

Ultrasound and Multidetector Computed Tomography. In most patients with a suspected bile duct injury or leak after LC, ultrasound and contrast-enhanced CT are the most common initial imaging studies performed. Both studies can be completed quickly and efficiently, even in the most critically ill patients, and ultrasound can be performed at the bedside in the

critical care setting. In most cases, both studies will demonstrate an intra-abdominal fluid collection, most often in the right upper quadrant (often the subhepatic space or gallbladder fossa) close to the surgical bed (see Figs. 81-1 and 81-3 to 81-7). CT, in particular, can better delineate peripheral enhancement and complexity and distinguish free bile fluid from a loculated biloma. Notably, however, neither imaging modality can distinguish a biloma from other common causes of a postoperative fluid collection, including a seroma, abscess, hematoma, or lymphocele; the distinction between these different entities is often based on the analysis of fluid obtained from surgical drains or the direct aspiration of a fluid collection under image guidance

Figure 81-11 Retained stone in CBD. ERCP 16 days after LC shows a calculus (arrow) in distal part of the CBD. Sphincterotomy was performed and the stone was removed.

Figure 81-12 Inadvertent ligation of CBD. ERCP shows CBD filling to level of surgical clips (arrow), indicating the site where the cystic duct had originated. No contrast material is identified proximally in the bile duct.

Figure 81-13 Bile duct injury during LC resulting in CBD stricture. A. ERCP shows abrupt narrowing (arrow) of CBD at level of cholecystectomy clips. **B.** Subsequent ERCP, with wire advanced proximal to stricture, better delineates site of stricture (arrow).

(CT or ultrasound). In addition, the location of a collection may not be helpful in distinguishing these entities; bile fluid can potentially disperse widely throughout the peritoneal cavity (see Figs. 81-1 and 81-3 to 81-7) and become loculated relatively distant to the site of bile leak, whereas lymphoceles, abscesses, seromas, and hematomas can develop in close contiguity with the biliary tree (i.e., gallbladder fossa or subhepatic space; see Fig. 81-10).^{33,34,53} In addition, neither ultrasound nor CT can accurately define the source of a leak, and cholangiography may be necessary to differentiate leaks originating from different sites in the biliary tree (see Figs. 81-3D, 81-5E, 81-6B, 81-8, and 81-9).

Both CT and ultrasound are also important tools in identifying evidence of biliary dilation, often before there is biochemical evidence of obstruction. New biliary dilation after a cholecystectomy should suggest either the presence of a retained CBD stone (with associated obstruction) or, alternatively, the development of a bile duct stricture. At the same time, a mild degree of biliary dilation after cholecystectomy is a normal finding and should not be overinterpreted as obstruction. Although the presence of bowel gas will often obscure the distal CBD and ampulla (perhaps in a majority of cases), in certain rare cases, ultrasound may be able to define a distal CBD stone as a highly echogenic focus with posterior acoustic shadowing.⁹ Alternatively, although the diagnosis can be difficult on CT, the use of multiplanar reformations and three-dimensional reconstructions can help define the course of the CBD along its entire length and may demonstrate a meniscus sign at the site of obstruction by a CBD stone. Depending on the calcium content of a stone, an obstructing retained stone may be radiodense and calcified or of soft tissue attenuation. Whereas bile duct injury or stricture is the other diagnostic possibility when one is confronted with progressive dilation of the biliary tree after cholecystectomy, the absence of bile duct dilation on CT or ultrasound does not exclude bile duct injury, and further investigations will often be necessary if these entities are strongly suspected clinically.^{33,38,53}

Hepatobiliary Scintigraphy. Hepatobiliary scintigraphy, most often performed with technetium Tc 99m mebrofenin (or a number of other technetium-based agents) has proved to be an extremely sensitive method for detecting both bile leaks and biliary obstruction (see Figs. 81-5D and 81-7C).^{32,70,71} In particular, hepatobiliary scintigraphy has proved to be extremely accurate in identifying bile leaks in the setting of a recent cholecystectomy, with a sensitivity that may approach 100%, even including leaks into diagnostically difficult locations, such as the lesser sac.⁷² Not only can the extravasation of radiotracer from the biliary system during scintigraphy reliably identify the presence of a leak, the absence of a leak can allow the clinician to confidently proceed with conservative management.^{33,70}

Nevertheless, hepatobiliary scintigraphy has certain key limitations, which can diminish its utility. Most important, whereas scintigraphy can identify the presence of leak, it cannot accurately delineate the site of leak, limiting its ability to guide further intervention. Moreover, although the modality can identify the leak, it provides no information about the severity of the leak or bile duct injury, again somewhat limiting its usefulness in terms of guiding subsequent therapy and intervention.³³ For example, scintigraphy cannot differentiate between the complete transection of a duct (which would typically require surgery) and a minimal tear of a duct (which could potentially be treated endoscopically).

Percutaneous Transhepatic Cholangiography. Whereas evaluation of the biliary system after a suspected bile duct injury almost always begins with ERCP, this modality struggles in certain situations; specifically, in performing ERCP, occlusion or transection of a large central bile duct is visualized as only a “stump” of the CBD, and the more proximal biliary tract cannot be visualized. This is of critical importance as the more proximal biliary tract must be visualized to facilitate surgical planning as well as to evaluate for other sites of potential bile duct injury. Moreover, injuries to the right posterior segmental bile duct draining segments VI and VII will often be missed on ERCP, and this is a commonly underdiagnosed and underappreciated site of bile duct injury during cholecystectomy.⁷³ As a result, percutaneous transhepatic cholangiography (PTC) is considered to be the “gold standard” radiographic examination in the evaluation of patients with suspected biliary injuries or strictures as it allows evaluation of the entire proximal biliary tree (even in cases with a significant distal bile duct injury) and the reliable identification of injuries to the right posterior segmental bile duct.

In most institutions, ERCP is typically performed first in the setting of a suspected bile duct injury to differentiate patients with a cystic duct leak or incomplete tear of a duct from those with a complete duct transection. Those patients with a completely transected duct then undergo PTC for evaluation of the proximal ductal system.⁷³ In addition to its valuable diagnostic role, PTC also serves as the first step in the placement of a percutaneous transhepatic catheter, allowing decompression of the biliary system either to treat or to prevent cholangitis resulting from biliary obstruction. Moreover, PTC can also facilitate the percutaneous treatment of biliary strictures, usually with balloon dilation.^{21,34,44}

Endoscopic Retrograde Cholangiopancreatography. ERCP is an excellent modality for both the diagnosis and management of many biliary complications after LC. In almost all cases, ERCP will be the first diagnostic study performed in the setting of a suspected leak, and in many cases, it may be the only required study.

With regard to biliary leaks, ERCP can identify the site of bile leak in more than 95% of cases, a clear advantage relative to other diagnostic studies, such as contrast-enhanced magnetic resonance imaging (MRI) and hepatobiliary scintigraphy, which cannot reliably identify the exact site of leakage (see Figs. 81-3D, 81-5E, 81-6B, 81-8, and 81-9). Compared with PTC, ERCP has a generally lower rate of complications and carries a lesser risk of iatrogenic bile duct injury, bile leak, cholangitis, and sepsis. ERCP is also a highly effective means of treating bile duct leaks as these complications can be managed endoscopically in more than 80% of cases (biliary stents with or without sphincterotomy).^{53,74} Nevertheless, ERCP is an invasive modality with an associated risk of postprocedural complications and the need for patient sedation.⁹

Whereas ERCP alone is sufficient in the diagnosis of low-grade strictures and injuries to the major central bile ducts, it is insufficient in patients with complete obstruction of the extrahepatic bile tree or with high ductal injuries as the intrahepatic bile ducts more proximally cannot be visualized. In these cases, PTC is needed to evaluate the intrahepatic ducts and to fully define the exact length of a patient's stricture.^{34,44,74} When both studies are performed, a gap of several centimeters may be present between a blind-ending distal duct demonstrated on ERCP and the proximal bile ducts opacified on PTC,

precluding percutaneous transhepatic stricture dilation.⁴⁴ As mentioned previously, the treatment for bile duct strictures is gradually moving away from surgical reconstruction and toward endoscopic management (usually balloon dilation and stenting; see Fig. 81-9), although surgery continues to play a major role in certain lesions.

Magnetic Resonance Cholangiopancreatography. During the last several years, the introduction of a number of different hepatobiliary contrast agents for MRI, the most important of which is gadoxetate disodium (Eovist; Bayer HealthCare Pharmaceuticals), has made MRI a highly valuable option for the detection of bile leaks. These agents, which are excreted into the biliary system in varying amounts, allow the acquisition of normal contrast-enhanced images in the arterial, venous, and delayed phases, followed by excellent opacification of the biliary system in the delayed hepatobiliary phase (usually at 10 to 20 minutes). This opacification of the biliary system has been improved with the introduction of gadoxetate disodium, 50% of which is excreted through the hepatobiliary system, compared with 3% to 5% of older hepatobiliary contrast agents, allowing faster and more avid enhancement of the bile ducts. A number of studies, conducted with a variety of different hepatobiliary agents, have suggested that contrast-enhanced MRI does very well in the identification of bile leaks, with a sensitivity up to 95% and a specificity up to 100%.⁷⁵⁻⁸⁰ Bile leaks on these images appear as areas of active extravasation of contrast material from the involved segment of the biliary tree into the peritoneum and perihepatic space. In the more chronic setting, contrast-enhanced MRI with hepatobiliary agents can also be potentially helpful in terms of identifying sites of biliary narrowing or obstruction as a result of biliary strictures. Although it is not completely necessary, conventional MRCP images (highly T2 weighted volumetric images) may be helpful as an ancillary imaging sequence to identify obstructing stones as well as to provide high-resolution volumetric images of the biliary tree to identify subtle sites of stricture or narrowing.⁷⁷

However, the use of these agents is limited in patients with cirrhosis, jaundice, or significant hepatobiliary disease as excretion of the contrast agent into the biliary system may be significantly impaired in such patients.⁷⁵⁻⁸⁰ This can be a significant obstacle to the use of this technique in patients with bile duct

injury or bile leak after cholecystectomy as many of these patients present with hepatobiliary dysfunction and jaundice. Moreover, as with other MRI examinations, the quality of images depends heavily on the patient's ability to adequately perform a breath-hold maneuver, a necessity that can be a problem in critically ill patients.⁹

Spilled Gallstones

Whereas LC has proved extremely effective during the last two decades, largely obviating the need for open cholecystectomy except in the most complicated cases, the use of this technique has resulted in an increased incidence of "spilled," "dropped," or "retained" gallstones during the procedure.⁸¹ Spilled gallstones result from perforation of the gallbladder during cholecystectomy, with subsequent spillage of stones into the intraperitoneal space. Unlike in open cholecystectomy, in which these stones are relatively easy to identify and to retrieve during the course of the procedure itself, surgeons performing LC may not realize that stones have been spilled or alternatively may not have adequate surgical exposure to retrieve the stones laparoscopically.⁸¹⁻⁸⁶ The incidence of gallbladder perforation during LC may be as high as 36%, and the rate of gallstone spillage may reach 19%.⁸⁷ Moreover, when spillage occurs, one series found that up to 50% of stones were lost and not retrieved during the procedure.^{82,88} If spilled stones are noted intraoperatively, the surgeon will often attempt to retrieve as many stones as possible. Nevertheless, given the low rate of associated complications, most surgeons will not convert the procedure to an open cholecystectomy to retrieve every possible stone, and some stones will undoubtedly be left behind.⁸⁹

Whereas spilled gallstones are common, the incidence of complications related to these stones is relatively rare, occurring in 8.5% of patients.^{82,84,85,87,89} Most patients are asymptomatic, and in many cases, stones are simply discovered as an incidental finding on an imaging examination (usually CT or MRI) (Figs. 81-14 to 81-16).⁸¹ Complications are thought to be more likely with infected stones (in the setting of acute cholecystitis), larger stone size (>1.5 cm), pigment stones, and increased age of the patient.^{83,90} The most common complication related to spilled stones is the development of an abscess surrounding the stones, either within the abdominal cavity (usually the subhepatic

Figure 81-14 Spilled gallstones, incidentally seen on CT 10 years after LC. **A.** Two small peripherally calcified gallstones medial to liver, adjacent to gastroesophageal junction (arrow). **B.** Slightly larger peripherally calcified gallstone caudal to liver (arrow).

space or in the retroperitoneum inferior to the subhepatic space) or within the anterior abdominal wall itself (Figs. 81-17 and 81-18).^{81,85,91,92} These abscesses can develop months or even years after surgery, and radiologists should always consider this a potential cause when confronted with a patient who develops an abdominal abscess of unknown etiology.⁸² The delay between cholecystectomy and abscess presentation can be considerable, probably as a result of the indolent nature of the inflammatory process and the often unusual sites of these abscesses.⁸⁶ In one review, the time interval between cholecystectomy and the onset of symptoms was 5.5 months (range, 0-36 months).^{85,86}

Figure 81-15 Spilled gallstones. Innumerable tiny dropped gallstones along Morison's pouch (arrows) in an asymptomatic patient several years after LC. Similar appearance of innumerable tiny gallstones was seen on preoperative ultrasound (not shown).

Other more rare complications include fistula formation, pain as a result of stones lodged in unusual locations (i.e., a hernia sac, ovary, fallopian tube), liver abscesses, bacteremia, adhesions, bowel obstruction, and even transdiaphragmatic migration of stones. Stones can migrate into the thorax either secondary to the erosion of gallstones through the diaphragm or from the formation of a subphrenic abscess, which subsequently connects supradiaphragmatically into the pleural space, lung, or bronchial tree.^{88,90} This can result in cholelithoptysis (expectoration of gallstones) or pleurolithiasis.^{46,85,93}

Imaging of Spilled Gallstones. Ultrasound, CT, and MRI may demonstrate spilled stones lying freely in the abdomen, often primarily around the liver.⁸⁶ On CT, the conspicuity of stones will vary dramatically, depending on their composition; pigment stones (with a high calcium content) usually are readily recognizable as calcified high-density nodules, whereas cholesterol stones and other stones with low calcium content can be difficult to identify or appear as small soft tissue nodules. Notably, when there is little or no calcium content on CT, spilled gallstones can very much mimic the appearance of peritoneal tumor implants or carcinomatosis.⁸¹ Stones, regardless of their type, are relatively easy to identify on MRI as most gallstones are highly hypointense on T2-weighted images.⁸²

Perhaps most important, when they are associated with infection, spilled stones likely serve as the nidus of an abscess, and the identification of a stone at the center of such a collection is critical in terms of management (see Figs. 81-17C and 81-18C). These collections are not treated with simple percutaneous drainage, but instead the stone (which represents the cause of the infection) must be retrieved either surgically (either open or laparoscopically) or percutaneously by an interventional radiologist.^{81,86} The majority of these abscesses are confined to the subhepatic space or the retroperitoneum inferior to the subhepatic space. Several unusual locations, however, have been described, including the thorax, subphrenic space, within the abdominal wall at trocar sites, and at the sites of incisional hernias.⁸⁶ These abscesses appear on CT as one or more fluid collections containing small opacities, ranging in density (based on their calcium content and stone type) from hypodense nodules to nodules that are partially or completely calcified.^{84,86,94} On ultrasound, echogenic shadowing foci within a fluid collection are typical of dropped stones, and the presence of calculi within a collection is virtually diagnostic of spilled stones complicated by abscess formation.⁸⁶

Figure 81-16 Spilled gallstones.

A. Several spilled gallstones incidentally detected in pelvis (arrows) adjacent to uterus.
B. Patient subsequently developed ascites; the spilled gallstones are more conspicuous (arrows).

Figure 81-17 Spilled gallstones resulting in perihepatic abscess. **A** and **B.** Noncontrast CT 3 days after LC shows a dropped gallstone in the porta hepatis (*long arrow, A*) and two dropped gallstones in Morison's pouch (*arrow, B*). Note surgical clip (*short arrow*) in gallbladder fossa. **C.** Patient presented 4 weeks after LC with fever and abdominal pain. Noncontrast CT shows interval development of an abscess surrounding the two dropped gallstones in Morison's pouch (*arrow*) and free fluid around the liver.

Figure 81-18 Spilled gallstones resulting in a large perihepatic abscess. Patient presented 9 months after LC with low-grade fever, fatigue, and lack of appetite. Contrast-enhanced CT (**A**) and axial T2-weighted MR (**B**) demonstrate a multiseptate abscess (*arrow*) caudal to right lobe of liver (L). The small calcified spilled gallstone within it, the nidus of the abscess, is seen only on noncontrast CT (**C**, *arrow*).

Biliary-Enteric Anastomosis

BACKGROUND, INDICATIONS, AND TECHNICAL CONSIDERATIONS

The creation of a biliary-enteric anastomosis has become a common component of multiple different surgical procedures and can be performed for a number of different reasons. The most common indications for the creation of such an anastomosis include liver transplantation; the resection of tumors involving the biliary tree, duodenum, or pancreatic head (often as part of a pancreaticoduodenectomy); benign or malignant biliary obstruction; biliary stones, biliary strictures, choledochal

cysts, or bile duct injuries; and inflammatory conditions of the biliary tree, such as primary sclerosing cholangitis.^{4,5}

Over time, reconstruction of the biliary system by a biliary-enteric anastomosis has most commonly been performed through the creation of a hepaticojejunostomy. Although choledochoduodenostomy and hepaticoduodenostomy are also viable alternatives, both have clear downsides. The use of the duodenum carries a significant risk of bile gastritis due to duodenogastric reflux.⁹⁵ Whereas a direct duct-to-duct anastomosis is also a possible option and is sometimes still used in liver transplantation, the creation of such an anastomosis is more technically difficult and carries much higher risks of anastomotic strictures and leaks (perhaps as high as 40%).⁹⁶ In

contrast, hepaticojejunostomy has proved to be safe and effective, with a much lower risk of bile leak (2.4%-5.6%).⁹⁶

There are minor variations in how a hepaticojejunostomy is created, depending on the presence or absence of a malignant neoplasm or a bile duct stricture and the exact site of this tumor or stricture. However, the surgical procedure usually includes the following. Once the abdomen is entered and the hepatoduodenal ligament is dissected free, the common duct must be identified. The common duct is usually the most anterior structure as it enters the liver, with the hepatic artery and portal vein running immediately posterior. This arrangement provides the surgeon with free access to the anterior aspect of the common duct. Importantly, the right hepatic duct typically will have a very short extrahepatic course, whereas the left hepatic duct is nearly entirely intrahepatic, features that have great significance as the surgeon dissects the ducts and prepares to create the anastomosis. Once the common duct is identified and dissected free, it is usually ligated distally, traction sutures are placed proximally, and the common duct is divided in between. In general, the common duct is carefully handled and dissected to avoid injury to its vascular supply, which would predispose the patient to strictures. If there is any pathologic process (i.e., stricture, malignant neoplasm) more proximally in the common duct near the confluence, the common duct may need to be resected in its entirety.^{96,97}

The jejunum is then transected 20 cm distal to the ligament of Treitz, and this limb of jejunum is brought up to the liver hilum in a retrocolic fashion. An anastomotic orifice is then created in the jejunal limb, and the proximal common duct (or the confluence of the ducts) is anastomosed to the jejunum. In those cases in which the common duct has been entirely sacrificed and the right and left hepatic ducts cannot be approximated for a common anastomosis, two separate anastomoses with the jejunum may be necessary. Notably, the anastomosis is almost always created by side-to-side technique, and depending on the surgeon, a transanastomotic stent may or may not be used.^{96,97}

The biliary-enteric anastomosis is usually best visualized on MDCT in the coronal or sagittal planes and can be difficult to identify on the source axial images. Pneumobilia is a common finding after the surgery, and this can be used to the radiologist's advantage in identifying the anastomosis as gas can sometimes be directly traced from the hepatic ducts into the jejunal limb. As mentioned earlier, some surgeons use a transanastomotic stent, and this can also be a valuable means of identifying the hepaticojejunostomy in the immediate perioperative period. In many cases, the right upper quadrant jejunal limb may be nondistended, further increasing the difficulty in adequately evaluating the anastomosis.⁹⁸

Hepaticojejunostomy may be associated with a number of different complications, including cholangitis, sepsis, liver abscesses, bile leaks, anastomotic strictures, hemorrhage, and pancreatitis. In addition, patients can present with a number of complications common to other major hepatobiliary surgeries, including delayed gastric emptying, bleeding, abscess formation, fistulas, and wound infections.⁹⁹

COMPLICATIONS

Biliary Leak

The rate of bile leaks after hepaticojejunostomy varies by the type of surgery performed. In general, the rate of bile leaks after

pancreaticoduodenectomy, pancreatectomy, and repair for bile duct injury ranges between 0% and 5%, whereas the incidence of bile leaks after liver transplantation (1%-25%) and biliary resection for cholangiocarcinoma (11%) is higher. A study by Antolovic and colleagues,⁴ looking at 519 patients who underwent hepaticojejunostomy in the setting of a number of different surgeries, found an overall leak rate of 5.6%.

Bile leaks are more commonly seen in the setting of liver transplantation as the jejunum is often not anastomosed to the common duct but rather to the right or left hepatic duct (or even smaller ducts). Bile leak rates also increase with cholangiocarcinoma resection because of the need for a concomitant liver resection, which often results in a bile leak from the liver surface rather than from the hepaticojejunostomy itself. Other risk factors include the use of preoperative chemotherapy (in patients with an underlying malignant neoplasm), high body mass index, diabetes, and lack of experience on the part of the surgeon (technical failure).⁴ However, one should note that the "bile leak rate" in many of these studies includes not simply bile leak from the hepaticojejunostomy anastomosis but also bile leak from the cut surface of the liver (if hepatic resection was performed) or leakage after the removal of a T tube.¹⁰⁰

In general, many minor bile leaks that do not involve the anastomosis can generally be managed conservatively, often with placement of a percutaneous drainage catheter into a collection identified on CT. In those patients with a minor leak for whom intervention is necessary, ERCP-guided stent placement can be difficult or impossible (particularly if there is associated anastomotic stricture), and PTC-guided treatment may be the best option. In cases of major leaks from the anastomosis itself, reoperation is often considered, although this can be extraordinarily difficult technically as the ductal tissue is often broken down and no longer suitable for reanastomosis.¹⁰¹

There are no imaging findings on MDCT that are absolutely specific for the diagnosis of anastomotic leak, although the presence of a fluid collection adjacent to the hepaticojejunostomy should certainly suggest this diagnosis. Nevertheless, a postoperative biloma due to anastomotic failure cannot be differentiated from a seroma, abscess, evolving hematoma, or lymphocele. As mentioned earlier, hepatobiliary scintigraphy can identify the presence of a leak but cannot definitively identify the source of a leak as originating from the anastomosis, whereas MRI with hepatobiliary contrast agents may be able to more precisely localize a leak to the anastomosis itself.

Biliary Stricture

The reported rate of stricture formation at the hepaticojejunostomy ranges from 5% to 17%, depending on the series.^{99,102,103} Hepaticojejunostomy strictures can be associated with the development of cholangitis and sepsis, and in a series by Schmidt and coworkers,¹⁰³ five of nine patients with a hepaticojejunostomy stricture ultimately developed biliary cirrhosis and one patient developed a cholangiocarcinoma at the stricture site. Risk factors for the development of a significant stricture include associated vascular injuries, active peritonitis at the time of repair, injury above or at the level of the biliary bifurcation, and prior biliary tract surgery or intervention.^{99,102}

A mild degree of intrahepatic biliary dilation after hepaticojejunostomy is not uncommon and should not automatically be assumed to represent an anastomotic stricture (or anastomotic tumor recurrence if the patient has a primary malignant neoplasm). However, the biliary system should be carefully

observed over sequential studies, and any significant or increasing biliary dilation should certainly raise suspicion for a stricture.⁹⁸ The treatment of hepaticojunostomy strictures is usually nonoperative and tends to rely on balloon dilation under PTC or ERCP guidance. Despite this, the recurrence rate after balloon dilation is relatively high (up to 20%), and multiple rounds of dilation may be necessary. However, in certain cases that are refractory to balloon dilation, surgical revision may be necessary.¹⁰⁴

Post-Traumatic Lesions of the Biliary Tree

Traumatic injury to the biliary tree and gallbladder is rare, with an incidence of less than 0.1%. In most cases, biliary tract injuries tend to be associated with significant injuries elsewhere in the abdomen and pelvis, including pancreatic, duodenal, hepatic, splenic, and vascular injuries.^{6,7}

Injury to the intrahepatic bile ducts is relatively common in the setting of hepatic trauma. In most cases, particularly when the injury is to a small peripheral intrahepatic duct, these injuries are self-limited, and bile leakage from these ducts is usually insignificant.³³ Only in rare cases is intervention or drainage required. Extrahepatic biliary tract injuries are more rare but may occur after both blunt and penetrating abdominal trauma.^{6,7} These injuries may be difficult to detect, and a high clinical index of suspicion is needed to avoid diagnostic delay as they are associated with high morbidity and mortality.⁸ Unlike injuries to the intrahepatic bile ducts, extrahepatic duct injuries are not typically self-limited and usually require intervention (often biliary stenting or surgical biliary diversion). Injuries to the extrahepatic bile duct, as a result of its anatomic location, have a high association with injuries to the hepatic artery and portal vein.³³

The most common location of traumatic biliary injury is the gallbladder, which is involved in up to 3% of patients after blunt abdominal trauma.¹⁰⁵⁻¹⁰⁹ Isolated injury to the gallbladder is rare as a result of the protective effects of the rib cage and liver. Accordingly, there are almost always concomitant injuries to adjacent organs, most notably the liver.* Not surprisingly, injury is most likely in a thin-walled or distended gallbladder, and alcohol intake may increase the likelihood of injury by raising pressures at the sphincter of Oddi. Alternatively, any thickening of the gallbladder wall, or even the presence of gallstones, is thought to have a protective effect.^{107-108,111}

Traumatic injuries to the gallbladder can be classified along a spectrum by the degree of severity: contusions, laceration/perforation, and gallbladder avulsion.^{8,105,107,108} In most cases, gallbladder injuries result from a direct blow to the right upper abdomen in a blunt trauma, although gallbladder avulsion can result from severe shear injuries as well.^{107,111} In many cases, contusion injuries, which represent hemorrhage into the gallbladder wall and lumen, go undiagnosed, and the majority of these patients probably never demonstrate clinical symptoms.¹¹² Gallbladder laceration, on the other hand, will often be manifested with frank perforation, resulting in a gallbladder leak.^{107,113} In rare cases, a laceration may not be manifested with perforation at initial clinical presentation, and patients may

subsequently develop delayed perforation after several days.¹¹⁴ Gallbladder avulsions, the most severe injuries, represent frank tearing of the gallbladder from the hepatic bed and are usually associated with a wide spectrum of other traumatic injuries in the abdomen.¹⁰⁷ The degree of separation of the gallbladder from the gallbladder fossa can vary, and the complete disruption of the gallbladder from all its attachments, including the cystic duct and artery, is termed a total avulsion.^{108,111,112}

IMAGING OF POST-TRAUMATIC LESIONS

Gallbladder injuries can be identified by a number of different radiologic modalities, including CT, ultrasound, hepatobiliary scintigraphy, and MRCP. However, in the acute setting, CT is certainly the most practical and effective means of making the diagnosis. Whereas many of the CT imaging features of gallbladder injury are nonspecific, there are several imaging findings that can be highly suggestive of the diagnosis, particularly when multiple findings are seen in conjunction. The presence of high-density blood products within the lumen of the gallbladder should raise strong suspicion for gallbladder injury (Fig. 81-19), although high-density stones, milk of calcium bile, vicarious excretion of contrast material into the gallbladder from a prior imaging study, and hyperdense biliary sludge could potentially mimic this finding. Other ancillary features that can also suggest the diagnosis include pericholecystic free fluid and hemorrhage (see Fig. 81-19), gallbladder hydrops (dilation), gallbladder wall thickening, irregularity and poor definition of the gallbladder wall, active extravasation of contrast material into the gallbladder lumen on arterial phase images, and even a focal defect or nonenhancement of a portion of the gallbladder wall (Fig. 81-20). One must be careful, however, as injury to the adjacent liver or right kidney could potentially account for some of these findings (especially pericholecystic

Figure 81-19 Trauma to gallbladder. CT 2 days after stab wound to the right upper quadrant shows gallbladder wall thickening with an intraluminal bile-blood level and infiltration of the pericholecystic tissue (black arrow). A subcutaneous right upper quadrant defect (white arrow) indicates the location of the penetrating knife. At surgery, two lacerations were found in the anterior and posterior aspect of the gallbladder with mild biliary peritonitis. Figure 81-20 Gallbladder avulsion. Alcoholic patient with cirrhosis after motor vehicle accident. **A.** Contrast-enhanced CT shows inhomogeneous enhancement of the gallbladder, with hypoenhancing (black arrows) and hyperenhancing areas (short white arrows). **B.** A thin membrane (arrowheads) surrounds the gallbladder, strongly suggesting the diagnosis of gallbladder avulsion, a finding confirmed at laparotomy. Moderate ascites, primarily secondary to cirrhosis. The hematocrit effect (long white arrow, **A** and **B**) in right paracolic gutter reflects component of hemoperitoneum.

hemorrhage and free fluid) and spuriously suggest the diagnosis of gallbladder injury.^{8,105,107,108}

Whereas CT is certainly the first-line imaging modality in the setting of trauma, other imaging modalities may be helpful if the CT findings of gallbladder injury are equivocal. Ultrasound may be able to detect subtle amounts of layering blood products within the gallbladder lumen that are not detectable

on CT; MRI, with its superior soft tissue resolution, may be able to identify subtle disruption or nonenhancement of the gallbladder wall that is beyond the resolution of CT. Ultimately, in those cases in which there is a strong clinical suspicion, or alternatively, when the CT findings are suggestive but not completely definitive, hepatobiliary scintigraphy may help identify leakage of bile from the injured segment of the biliary tree.¹⁰⁷

Gallbladder and Biliary Tract: Differential Diagnosis

RICHARD M. GORE

CHAPTER OUTLINE

Gallbladder Imaging

- Table 82-1. Gallbladder Filling Defects
- Table 82-2. Enlarged Gallbladder
- Table 82-3. Small Gallbladder
- Table 82-4. Gallbladder Wall Thickening
- Table 82-5. Pericholecystic Fluid
- Table 82-6. Multiseptate Gallbladder
- Table 82-7. Gas in the Gallbladder or Biliary Tract
- Table 82-8. Cholecystenteric and Biliary-Enteric Fistula

Ultrasound

- Table 82-9. Focal, Mobile, Shadowing Gallbladder Reflectors
- Table 82-10. Focal, Mobile, Nonshadowing Gallbladder Reflectors
- Table 82-11. Focal, Nonmobile, Shadowing Gallbladder Reflectors
- Table 82-12. Hyperechoic Foci in Gallbladder Wall
- Table 82-13. Nonvisualization of the Gallbladder by Ultrasound
- Table 82-14. Artifacts That Mimic Gallstones
- Table 82-15. Structures That Sonographically Mimic the Gallbladder

Computed Tomography

- Table 82-16. Increased Attenuation of Gallbladder Lumen

Nuclear Medicine

- Table 82-17. Nonvisualization of the Gallbladder by Scintigraphy
- Table 82-18. Delayed Visualization of the Gallbladder
- Table 82-19. Nonvisualization of the Isotope in Bowel
- Table 82-20. Delayed Bowel Activity
- Table 82-21. Rim Sign

Biliary Tract Imaging

- Table 82-22. Filling Defects or Segmental Lesions of Bile Ducts
- Table 82-23. Bile Duct Narrowing or Obstruction
- Table 82-24. Biliary Dilation
- Table 82-25. Biliary Dilation Without Jaundice
- Table 82-26. Biliary Obstruction Without Dilation
- Table 82-27. Cystic Dilation of the Bile Ducts

Imaging Findings in Specific Gallbladder and Biliary Diseases

- Table 82-28. Acute Cholecystitis
- Table 82-29. Chronic Cholecystitis
- Table 82-30. Sclerosing Cholangitis
- Table 82-31. Primary Biliary Cirrhosis
- Table 82-32. Cholangiocarcinoma
- Table 82-33. Gallbladder Carcinoma
- Table 82-34. Cystic Biliary Disease: Caroli's Disease, Choledochal Cyst, Choledochocoele

Gallbladder Imaging

TABLE 82-1 Gallbladder Filling Defects

COMMON

Gallstones
Sludge
Mucosal folds
Partial volume artifact (ultrasound, CT)
Adenomyomatosis
Cholesterosis
Pseudomass-duodenal impression (ultrasound)
Air volume averaging with adjacent bowel (CT, MR)

UNCOMMON

Carcinoma
Metastases, especially melanoma, lung, kidney, esophagus
Adenoma
Papilloma

Villous hyperplasia
Epithelial cyst
Mucus retention cyst
Worms and parasites: *Ascaris*, *Paragonimus*, *Clonorchis*, *Filaria*, *Schistosoma*, *Fasciola*
Fibrinous debris
Desquamated mucosa
Metachromatic leukodystrophy
Ectopic pancreatic, gastric, hepatic, intestinal, prostatic tissue
Varices
Inflammatory polyp
Food through enterobiliary fistula
Fibroadenoma
Neurinoma
Hemangioma

TABLE 82-2 Enlarged Gallbladder**COMMON**

Cystic duct or common bile duct obstruction
 Hyperalimentation
 Post surgery
 Prolonged fasting
 Vagotomy
 Diabetes mellitus
 AIDS
 Mucocele
 Empyema
 Hydrops
 Hepatitis
 Pancreatitis
 Alcoholism
 Narcotic analgesia
 Anticholinergics

UNCOMMON

Kawasaki's syndrome
 Leptospirosis
 Scarlet fever
 Acromegaly

TABLE 82-3 Small Gallbladder

Chronic cholecystitis
 Congenital multiseptate gallbladder
 Postprandial study
 Cystic fibrosis
 Congenital hypoplasia
 Congenital multiseptate gallbladder
 Hypoplastic gallbladder

TABLE 82-4 Gallbladder Wall Thickening**COMMON**

Acute cholecystitis
 Chronic cholecystitis
 Hyperplastic cholecystosis
 Hepatitis
 Portal hypertension
 Right-sided heart failure
 Hypoproteinemia or hypoalbuminemia
 Gallbladder carcinoma
 Renal failure
 Total parenteral nutrition
 Cirrhosis
 Sepsis
 Infectious mononucleosis
 Acute pancreatitis
 AIDS
 Postprandial study
 Pyelonephritis of right kidney

UNCOMMON

Sclerosing cholangitis
 Schistosomiasis
 Xanthogranulomatous cholecystitis
 Extrahepatic portal vein obstruction
 Lymphatic obstruction
 Gallbladder wall varices
 Multiple myeloma
 Lymphoma
 Obstructed gallbladder lymphatics
 Acute myelogenous leukemia
 Brucellosis
 Graft-versus-host disease

TABLE 82-5 Pericholecystic Fluid

Pericholecystic abscess
 Pancreatitis
 Acute cholecystitis
 Pericholecystic abscess
 Ascites
 AIDS
 Peritonitis

TABLE 82-6 Multiseptate Gallbladder

Desquamated gallbladder mucosa
 Congenital malformation
 Normal folded gallbladder
 Cholesterosis
 Adenomyomatosis

TABLE 82-7 Gas in the Gallbladder or Biliary Tract**COMMON**

Postoperative (e.g., status post sphincterotomy or Whipple's procedure)
 Biliary-enteric fistula (see Table 82-8)
 Pancreatitis
 Emphysematous cholecystitis

UNCOMMON

Common duct entry into duodenal diverticulum
 Crohn's disease
 Incompetent sphincter
 Carcinoma of the gallbladder, ampulla, duodenum, bile ducts, stomach, colon
 Metastases
 Lymphoma
 Trauma
 Status post intubation or ERCP
 Parasites: *Strongyloides*, *Clonorchis*, *Ascaris*, ruptured amebic abscess of liver

TABLE 82-8 Cholecystenteric and Biliary-Enteric Fistula**COMMON**

Gallstone fistula from gallbladder or bile ducts
 Postoperative (e.g., Whipple's procedure)

UNCOMMON

Carcinoma of the gallbladder, bile ducts, duodenum, colon, stomach
 Peptic ulcer perforation into biliary tract
 Crohn's disease
 Diverticulitis of the duodenum or hepatic flexure
 Actinomycosis
 Tuberculosis
 Trauma
 Lymphoma
 Perforating cholecystitis

Ultrasound**TABLE 82-9** Focal, Mobile, Shadowing Gallbladder Reflectors

Gallstones
 Intraluminal gas
 Calcified parasites: *Ascaris*, *Clonorchis*, *Fasciola*

TABLE 82-10 Focal, Mobile, Nonshadowing Gallbladder Reflectors

Small stones not in transducer focal zone
 Blood clots
 Pus
 Sludge balls
 Parasites: *Ascaris*, *Clonorchis*, *Fasciola*
 Precipitated contrast material from ERCP
 Fibrinous debris
 Desquamated mucosa

TABLE 82-11 Focal, Nonmobile, Shadowing Gallbladder Reflectors

Stone or crystal in Rokitsky-Aschoff sinus
 Impacted gallstone
 Spiral valve folds
 Polyp-containing cholesterol
 Adherent gallstone

TABLE 82-12 Hyperechoic Foci in Gallbladder Wall

Polyps
 Adherent stones
 Intramural gas in emphysematous cholecystitis
 Intramural microabscesses
 Rokitsky-Aschoff sinuses

TABLE 82-13 Nonvisualization of the Gallbladder by Ultrasound**COMMON**

Postprandial contraction
 Post cholecystectomy
 Chronic cholecystitis
 Technical factors: obese patient or thin patient with superficial gallbladder
 Ectopic gallbladder
 Gallbladder obscured by gas

UNCOMMON

Carcinoma of the gallbladder
 "Porcelain" gallbladder
 Gangrenous cholecystitis
 Emphysematous cholecystitis
 Metastases to the gallbladder
 Acute hepatic dysfunction (e.g., hepatitis)
 Congenital absence (0.03% of population)

TABLE 82-14 Artifacts That Mimic Gallstones

Partial volume artifact with duodenal impression
 Refraction from folds in gallbladder neck
 Inspissated sludge
 Any cause of intraluminal defect

TABLE 82-15 Structures That Sonographically Mimic the Gallbladder

Fluid-filled duodenal bulb
 Dilated cystic duct remnant
 Hepatic cyst
 Renal cyst
 Omental cyst
 Ligamentum teres abscess
 Choledochal cyst

Computed Tomography

TABLE 82-16 Increased Attenuation of Gallbladder Lumen

Gallstones
 Sludge
 Debris
 Vicarious excretion of contrast medium
 Hemobilia
 Milk of calcium bile
 Mucinous adenocarcinoma of the gallbladder
 Volume averaging with adjacent structures
 Hydrops
 Hemorrhagic cholecystitis
 Prior ERCP or oral cholecystography

Nuclear Medicine

TABLE 82-17 Nonvisualization of the Gallbladder by Scintigraphy**COMMON**

Acute cholecystitis

UNCOMMON

Prolonged fasting
 Carcinoma of the gallbladder
 Chronic cholecystitis
 Severe hepatocellular disease
 Complete common bile duct obstruction
 Acute pancreatitis
 Nonfasting patient
 Gallbladder hydrops
 Post cholecystectomy
 Hyperalimentation

RARE

Alcoholism
 Choledochal cyst
 Dubin-Johnson syndrome
 Kawasaki's syndrome
 Mirizzi syndrome

TABLE 82-18 Delayed Visualization of the Gallbladder**COMMON**

Chronic cholecystitis

UNCOMMON

Acalculous cholecystitis
 Pancreatitis
 Hepatocellular disease
 Total parenteral nutrition
 Carcinoma of the gallbladder
 Dubin-Johnson syndrome

TABLE 82-19 Nonvisualization of the Isotope in Bowel**COMMON**

Cholelithiasis

UNCOMMON

Obstructive pancreatic carcinoma
 Drug-induced cholestasis
 Sphincter of Oddi spasm secondary to morphine
 Severe hepatocellular disease
 Biliary atresia

RARE

Pancreatitis
 Cholangiocarcinoma
 Sepsis
 Choledochal cyst with complete obstruction
 Portal vein thrombosis
 Surgical ligation of common bile duct

TABLE 82-20 Delayed Bowel Activity**COMMON**

Cholelithiasis with incomplete obstruction
 Severe hepatocellular disease

UNCOMMON

Acute and chronic cholecystitis
 Sphincter of Oddi spasm, stricture, or tumor
 Ascending cholangitis
 Choledochal cyst with incomplete obstruction

TABLE 82-21 Rim Sign**COMMON**

Acute cholecystitis
 Gangrenous cholecystitis
 Emphysema of the gallbladder
 Gallbladder perforation

UNCOMMON

Chronic cholecystitis
 Adjacent hepatic inflammatory process
 Hepatic amebic abscess

Biliary Tract Imaging**TABLE 82-22 Filling Defects or Segmental Lesions of Bile Ducts****COMMON**

Gallstone
 Air bubble
 Blood clot
 Sphincter of Oddi or Boyden spasm (pseudocalculus)
 Ampullary edema
 Sludge or debris
 Cholangiocarcinoma
 Carcinoma of the ampulla, duodenum, or pancreas
 Stricture
 Postoperative defect
 Dilated crossing vessel
 Mirizzi syndrome

UNCOMMON

Metastases
 Neoplasms: adenoma, papilloma, spindle cell, hamartoma, polyp, sarcoma
 Parasites: *Ascaris lumbricoides*, *Clonorchis sinensis*, *Fasciola hepatica*, *Echinococcus granulosus*
 Enlarged lymph node
 Hydatid cyst eroding into biliary tree

TABLE 82-23 Bile Duct Narrowing or Obstruction**MALIGNANT STRICTURES**

Cholangiocarcinoma
 Hepatoma
 Ampullary carcinoma
 Lymphoma
 Metastasis from neoplasms of pancreas, gallbladder, stomach, lymph nodes, hepatic parenchyma, hepatoduodenal ligament

BENIGN STRICTURES**Acquired**

Cholangitis
 Cholelithiasis
 Papillary stenosis
 Sclerosing cholangitis
 Cholangiolytic hepatitis
 Mirizzi syndrome
 Duodenal diverticulum

Iatrogenic or Traumatic

Surgical injury
 Hepatic artery chemotherapy
 Trauma
 Radiation therapy
 Hepatic artery embolization

Infectious

Imaging Findings in Specific Gallbladder and Biliary Diseases**TABLE 82-28** Acute Cholecystitis**SONOGRAPHIC FINDINGS**

Gallbladder wall thickening >3 mm
Gallbladder wall lucency (halo sign): three-layer configuration with sonolucent middle layer
Striated wall thickening: alternating echogenic and hypodense mural bands
Gallbladder distention >5 cm in anteroposterior diameter
Sonographic Murphy sign
Pericholecystic fluid
Pseudomembrane formation
Gallstones

NUCLEAR SCINTIGRAPHY

Nonvisualization of the gallbladder despite the presence of isotope in the bile ducts and duodenum
Rim sign: increased activity in the gallbladder fossa conforming to the inferior hepatic edge

COMPUTED TOMOGRAPHY

Gallstones, mural thickening, pericholecystic fluid
Increased gallbladder wall enhancement
Focal or nonuniform contrast-enhanced thickening
Mural nodularity, loss of crisp demarcation between gallbladder and liver, mild infiltration of pericholecystic fat
Elevated attenuation of gallbladder bile because of hemorrhage or empyema
Low-density edema in the hepatocholecystic space
Transient hepatic attenuation difference in adjacent liver

MR IMAGING

Gallstones, mural thickening, pericholecystic fluid
Gallbladder wall and adjacent tissues demonstrate increased enhancement on gadolinium-enhanced, fat-suppressed images
Transient hepatic intensity difference in adjacent liver

TABLE 82-29 Chronic Cholecystitis**SONOGRAPHIC FINDINGS**

Gallstones
Smooth irregular gallbladder wall thickening >3 mm
Noncontractility or decreased response after cholecystokinin injection

NUCLEAR SCINTIGRAPHY

Normal, delayed, or absent gallbladder visualization
Visualization of bowel before gallbladder
Noncontractility or decreased response after cholecystokinin injection

COMPUTED TOMOGRAPHY

Mural thickening and gallstones
Lack of contrast enhancement of gallbladder bile
Small, contracted gallbladder

MR IMAGING

Small, irregularly shaped gallbladder with a thickened, mildly enhancing wall on gadolinium-enhanced, fat-suppressed images

TABLE
82-30**Sclerosing Cholangitis****LOCATION**

Intrahepatic and extrahepatic ducts involved (90%)
 Intrahepatic ducts only (1%-5%)
 Extrahepatic ducts only (5%-10%)
 Cystic duct involved (18%)

CHOLANGIOGRAPHY

Multifocal strictures with predilection for bifurcations
 Small saccular outpouchings
 Beaded appearance with alternating segments of dilation and stenosis
 "Pruned tree" appearance with opacification of central ducts and nonfilling of more peripheral ducts
 Intrahepatic ductal dilation
 Coarse, nodular mural irregularities
 Gallbladder irregularities

COMPUTED TOMOGRAPHY

Skip dilation, stenosis, pruning, beading of intrahepatic bile ducts
 Dilation, stenosis, enhancing mural nodularity, thickening, and contrast enhancement of the bile ducts
 Mural thickening of the gallbladder
 Periportal adenopathy
 Caudate lobe hypertrophy
 Atrophy of lateral segment of left lobe of liver

ULTRASOUND

Brightly echogenic portal triads
 Mural thickening of the gallbladder and extrahepatic bile ducts
 Focal areas of intrahepatic biliary dilation
 Periportal adenopathy
 Caudate lobe hypertrophy
 Atrophy of lateral segment of left lobe of liver

MR IMAGING

Mild duct wall thickening, beading, skip dilations
 Periportal inflammation with mural and periportal enhancement on gadolinium-enhanced T1-weighted imaging
 Peripheral, wedge-shaped zones of hyperintense signal on T2-weighted imaging
 Increased signal intensity in liver on T1-weighted imaging not corresponding to fat
 Patchy, segmental, peripheral parenchymal enhancement on immediate postgadolinium injection images
 Periportal adenopathy
 Caudate lobe hypertrophy
 Atrophy of lateral segment of left lobe of liver

HEPATOBILIARY SCINTIGRAPHY

Multiple focal areas of isotope retention in the intrahepatic biliary tree
 Prolongation of hepatic clearance
 Gallbladder visualized in only 70% of cases

TABLE
82-31**Primary Biliary Cirrhosis****CHOLANGIOGRAPHY**

Only intrahepatic ducts are involved
 Tortuous intrahepatic ducts with narrowing, caliber variation, decreased arborization—the "tree in winter" appearance

HEPATOBILIARY SCINTIGRAPHY

Marked prolongation of hepatic isotope clearance
 Uniform hepatic isotope retention
 Normal visualization of the gallbladder and bile ducts

COMPUTED TOMOGRAPHY AND ULTRASOUND

Gallstones (40%)
 Hepatomegaly (50%)
 Periportal adenopathy
 Caudate lobe hypertrophy

MR IMAGING

Periportal halo sign due to periportal fibrosis
 Periportal adenopathy
 Caudate lobe hypertrophy

TABLE 82-32 Cholangiocarcinoma**LOCATION**

Distal common bile duct (30%-50%)
 Proximal common bile duct (15%-30%)
 Common hepatic duct (14%-37%)
 Confluence of hepatic ducts (10%-26%)
 Left or right hepatic duct (8%-13%)
 Cystic duct (6%)

CHOLANGIOGRAPHY

Long, or rarely short, concentric focal stricture with wall irregularities
 Exophytic intraductal tumor mass, 2 to 4 mm in diameter
 Prestenotic diffuse focal biliary dilation
 Progression of ductal strictures

ULTRASOUND

Biliary dilation
 Hyperechoic (75%), hypoechoic (14%), or isoechoic mass (14%)

COMPUTED TOMOGRAPHY

Predominantly homogeneous, hypodense mass with irregular borders
 No enhancement or mild ring enhancement on portal venous phase
 Diffuse contrast enhancement seen on delayed (10-15 minutes) image because of the nature of the vascularity of this tumor
 Ancillary findings: hepatic lobar atrophy associated with crowding of ducts; asymmetric, intrahepatic bile duct dilation; segmental or lobar attenuation abnormalities

MR IMAGING

High-grade biliary obstruction and bile duct wall thickness >5 mm
 Tumor is isointense or low signal relative to liver on T1-weighted images
 Tumor signal intensity on T2-weighted images ranges from markedly increased to mildly increased relative to liver
 Tumor enhances moderately on gadolinium-enhanced T1-weighted images
 Ductal tumors arising in intrapancreatic portion of common bile duct are well delineated as low signal intensity masses highlighted by the high signal intensity of the pancreatic head on fat-suppressed T1-weighted images

SCINTIGRAPHY

Biliary obstruction on hepatobiliary scan
 Intrahepatic tumors are cold on sulfur colloid and hepatobiliary scans
 Mass may show focal uptake on gallium scan

ANGIOGRAPHY

Hypervascular tumor with neovascularity (50%)
 Poor or absent tumor stain
 Arterioarterial collaterals along the course of the bile ducts associated with arterial obstruction
 Displacement, encasement, or occlusion of the hepatic artery and portal vein

TABLE 82-34 Cystic Biliary Disease: Caroli's Disease, Choledochal Cyst, Choledochocoele**CAROLI'S DISEASE**

Multiple cystic structures that converge toward the porta hepatis as either localized or diffusely scattered cysts communicating with bile ducts
 Segmental saccular or beaded appearance of the intrahepatic ducts
 Extrahepatic ducts frequently ectatic
 Sludge and calculi often present in these dilated ducts

CHOLEDOCHAL CYST**Location**

Intrahepatic and extrahepatic ducts (73%)
 Extrahepatic ducts alone (27%)
 Dilated left and right main intrahepatic ducts (45%); bilateral (58%); unilateral (42%), left lobe only

Cholangiography

Dilated duct diameter (2-15 cm)
 Abrupt change in ductal caliber at site of cyst

Computed Tomography and Ultrasound

Large, fluid-filled structure beneath the porta hepatis separate from the gallbladder, which communicates with the hepatic ducts
 Abrupt caliber change at junction of dilated segment and normal ducts
 Intrahepatic biliary dilation

Hepatobiliary Scintigraphy

Late filling and stasis of isotope within cyst
 Dilation of intrahepatic biliary system

Upper Gastrointestinal Tract Series

Soft tissue mass in right upper quadrant
 Anterior displacement of the second portion of the duodenum and distal stomach
 Widening of the duodenal sweep
 Inferior displacement of the duodenum
 Extrinsic compression of the proximal duodenum

CHOLEDOCHOCOELE

Smooth clublike or saclike dilation of the intramural segment of the common bile duct
 Smooth, well-defined intraluminal duodenal filling defect in the region of the papilla on barium studies that changes shape with compression and peristalsis

TABLE 82-33 Gallbladder Carcinoma

Replacement of gallbladder by tumor (40%-65%)
 Focal or diffuse, asymmetric, irregular thickening of the gallbladder wall (20%-30%)
 Bulky tumor involving the gallbladder fossa, adjacent liver, and hepatoduodenal ligament
 Granular punctate calcifications with mucinous adenocarcinoma
 Liver metastases; enlarged regional lymph nodes; intraperitoneal seeding; invasion of adjacent duodenum, colon, right kidney, stomach
 Mass has increased signal intensity on T2-weighted MR sequences

Computed Tomography
Magnetic Resonance Imaging
Selecting an Appropriate Imaging Technique

Normal Anatomy

The liver is the largest abdominal organ and occupies the majority of the upper right quadrant of the abdomen. The diaphragm borders the liver superiorly, laterally, and anteriorly. The stomach, duodenum, and transverse colon border the liver medially; the hepatic colonic flexure, inferiorly; and the right kidney and adrenal gland, posteriorly. The liver is encapsulated by a dense layer of connective tissue, eponymously named Glisson's capsule. Peritoneum covers the liver, except in the regions of the gallbladder fossa, the fossa for the inferior vena cava (IVC), and the bare area. The surface morphology of the liver features a convex diaphragmatic surface and a concave visceral surface. The bare area abuts the diaphragmatic surface posteriorly and is demarcated by the coronary ligament. The coronary ligament itself is formed by folds of parietal and visceral peritoneum. The superior and inferior limbs of the coronary ligament fuse to form the right and left triangular ligaments laterally (Fig. 83-1). The right and left limbs of the coronary ligament fuse ventrally and extend as the falciform ligament that contains the ligamentum teres, which extends from the umbilicus to the superior surface of the liver.¹

The porta hepatis is a transverse slit in the hilum of the liver that is perforated by the right and left hepatic ducts, hepatic artery, and portal vein. The common bile duct, hepatic artery, portal vein, nerves of the liver, and lymphatics lie enclosed within the layers of the hepatoduodenal ligament (free edge of lesser omentum). The gastrohepatic ligament, which forms the superior aspect of the lesser omentum, attaches the liver to the lesser curvature of the stomach.

HEPATIC BLOOD SUPPLY

The liver has a dual blood supply from the hepatic artery, which provides systemic arterial circulation, and the portal vein, which returns blood from the gastrointestinal tract and spleen.² Hepatic arterial flow provides about 25% of the hepatic blood supply. The majority of the blood supply of the liver comes from mesenteric portal drainage because of the liver's role in gastrointestinal physiologic activity.³ Factors that influence the relative contribution of arterial and portal venous blood flow include hormonal, autonomic neural, and nutritional factors. The balance of blood supply may also become dysregulated by disease, such as hepatic parenchymal disease.^{1,4}

Portal Vein

The portal vein arises from the confluence of the superior mesenteric and splenic veins and is located posterior to the neck of the pancreas (Figs. 83-2 and 83-3). The portal vein courses superiorly and toward the right, just posterior to the common bile duct and hepatic artery, within the hepatoduodenal ligament. At the porta hepatis, the portal vein divides into left and right branches. The right branch courses horizontally and bifurcates into anterior and posterior branches. The left branch is horizontal initially but then courses cranially and terminates into ascending and descending branches. The left portal vein joins the obliterated umbilical vein within the fissure of the ligamentum teres hepatis.^{2,4-6} In embryonic life, the umbilical vein is patent and blood from the umbilical vein drains into the left portal vein, where much of it is shunted through the ductus venosus.

Many anatomic variations of the portal vein exist. Most common is absence of the right portal vein with anomalous branches from the main portal vein and the left portal vein. Absence of the horizontal segment of the left portal vein is more rare.

Hepatic Artery

The celiac axis divides into the common hepatic, splenic, and left gastric arteries at the level of T12-L1. The common hepatic artery courses along the upper border of the pancreatic head, anteriorly and to the right, behind the posterior layer of peritoneum of the lesser sac. After giving off the gastroduodenal artery, the common hepatic artery becomes the proper hepatic artery. The proper hepatic artery enters the subperitoneal space of the hepatoduodenal ligament at the upper margin of the duodenum.⁴ The proper hepatic artery ascends to the liver, anterior to the portal vein and medial to the common bile duct. After entering the porta hepatis, the proper hepatic artery divides into the right, left, and occasionally middle hepatic arteries. The right and left hepatic arteries supply the right and

Figure 83-1 Peritoneal and visceral relationships of the liver. Diaphragmatic (A) and visceral (B) surfaces of the liver from a radiologic perspective.

Figure 83-2 Origin of the portal vein. (From Sherlock S: *The portal venous system and portal hypertension*. In Sherlock S [ed]: *Diseases of the Liver and Biliary System*. Oxford, Blackwell Scientific, 1985, pp 134–181.)

Figure 83-3 Portal venous anatomy. Maximum intensity projection image of CT of upper abdomen demonstrates confluence of superior mesenteric vein (single arrowhead) and splenic vein (double arrowheads) forming main portal vein (arrow). The main portal vein divides into right and left branches (double arrows) at the porta.

left lobes of the liver, respectively. The middle hepatic artery, if present, supplies the medial segment of the left lobe, augmented by branches of the left hepatic artery. Branches of the right hepatic artery supply the caudate lobe; but in some variations, the left or middle hepatic artery may make perfusional contributions.^{2,5} The right hepatic artery also gives off the cystic artery to the gallbladder.

This classic arrangement of the hepatic arterial anatomy is seen in only 55% of patients (Figs. 83-4 and 83-5).² Common variants include the right hepatic artery partially (18%) or completely (14%) replaced by a branch from the superior mesenteric artery, the entire hepatic artery arising from the superior mesenteric artery (2%-4%), a partially or completely replaced

origin of the left hepatic artery from the left gastric artery (18%-25%), and the left hepatic artery giving rise to the middle hepatic artery (45%).^{4,5}

Hepatic Veins

The right, middle, and left hepatic veins lie within the postero-superior aspect of the liver. These veins course through the liver superiorly and obliquely and drain into the IVC. Several small emissary hepatic veins drain the caudate lobe independently into the IVC. The diameter of the hepatic veins is variable and may increase transiently with the Valsalva maneuver. Persistent dilation of the IVC and hepatic veins may be seen with right-sided congestive heart failure.

Figure 83-4 Variations in the anatomy of the hepatic arteries.

A. Normal pattern. Right hepatic artery posterior to common hepatic duct. **B.** Right hepatic artery anterior to common hepatic duct. **C.** Right hepatic artery from superior mesenteric artery (sole or accessory). **D.** Common hepatic artery from superior mesenteric artery. **E.** Left hepatic artery from left gastric artery.

Figure 83-5 Hepatic arterial anatomy. Maximum intensity projection image of CT of upper abdomen demonstrates left gastric artery (arrow), splenic artery (double arrows), and common hepatic artery (small arrow) arising from the celiac axis. The common hepatic artery continues as the proper hepatic artery (double arrowheads) after giving off the gastroduodenal artery (double small arrows). The proper hepatic artery divides into right and left branches (arrowheads) at the porta.

Duplication of the right, middle, and left hepatic veins is seen in 20%, 5%, and 15% of subjects, respectively.⁷ Absence of the main hepatic veins occurs in 8% of subjects.⁸ Accessory hepatic veins may also be seen in the liver. In one third of the population, the most common accessory hepatic vein drains the anterosuperior segment of the right hepatic lobe, which empties into the middle hepatic vein or occasionally into the right hepatic vein. Rarely, a separate inferior right hepatic vein drains directly into the IVC.⁷

LOBAR AND SEGMENTAL HEPATIC ANATOMY

The liver can be divided into the right, left, and caudate lobes. The interlobar fissure separating the right and left lobes is oriented along a line passing through the gallbladder fossa inferiorly and the middle hepatic vein superiorly. Although this fissure is well formed in some patients, it may be incomplete in others. The fissure for the ligamentum teres forms the left intersegmental fissure, which divides the left lobe into medial and lateral segments. The fissure for the ligamentum venosum separates the left lateral hepatic segment from the caudate lobe.

Advances in surgical techniques of liver lesion resection have made conventional hepatic lobar anatomy obsolete, however. Surgeons need precise localization of liver lesions in the functional segments rather than in lobes for planning resection. The functional segmentation of the liver is based on surgical definition of feasible intrahepatic boundaries for resection. The segmental anatomy of the liver is primarily based on vascular anatomy that can be illustrated on cross-sectional imaging (Fig. 83-6).⁹⁻¹³ Each segment has an independent vascular supply and biliary drainage. The portal venous, hepatic arterial, and bile duct branches course through the segments (intrahepatic). The main hepatic veins course in between the segments (intersegmental).⁹⁻¹³ The segmental nomenclature most commonly followed is the Bismuth-Couinaud system (Fig. 83-7).^{14,15}

The Bismuth-Couinaud system serves as the anatomic basis for localizing focal hepatic lesions. In this system, the liver is divided into one segment and eight subsegments. The vertical divisions along planes of the main hepatic veins are maintained and are further divided by a horizontal plane passing through the right and left portal veins. The plane through the middle hepatic vein separates the right lobe from the left lobe. By these vascular landmarks, segmental localization of liver lesions can be performed with cross-sectional imaging.^{16,17}

Segment I is the caudate lobe. The caudate lobe is a pedunculated portion of the liver extending medially from the right lobe between the portal vein and the IVC (Fig. 83-8). It has some unique features.^{18,19} Functionally, the caudate lobe is an autonomous part of the liver, with a separate blood supply, bile drainage, and venous drainage. The right border of the caudate lobe is continuous with the parenchyma of the right hepatic lobe by an isthmus. Posteriorly, the IVC borders the caudate lobe. Inferiorly, the caudate lobe forms the superior margin of the foramen of Winslow and divides into a left-sided anterior prominence called the papillary process and a transverse caudate process that protrudes laterally to join the right hepatic lobe. The papillary process can be prominent and penetrate the lesser sac behind the gastric antrum close to the hepatic artery and the portal vein.^{18,19} In some cases, it may simulate a pseudolesion, misinterpreted as an enlarged lymph node or pancreatic mass on cross-sectional images.²⁰

The next consecutive segment numbers are given to segments of the left lobe, followed by the right lobe, in a clockwise fashion as seen in the frontal projection, with the exception of segment IVa. The lateral segments II and III of the left lobe lie lateral and to the left of the left hepatic vein. Segment II lies above and segment III lies below the plane of the portal vein. Segment IV lies between the middle and left hepatic veins. Segment IVa and segment IVb lie above and below the plane of the portal vein, respectively. In the right lobe, the right hepatic vein separates the anterior segments (V and VIII) from the posterior segments (VI and VII). The superior segments (VII

Figure 83-6 Segmental anatomy of the liver. **A.** Anteroposterior “see-through” diagram of the liver demonstrates the major venous anatomy and the levels of multiple axial sections used to depict segmental hepatic anatomy. IVC, Inferior vena cava; RHV, right hepatic vein; MHV, middle hepatic vein; LHV, left hepatic vein; LT, ligamentum teres; LPV, left portal vein; MPV, main portal vein; RPV, right portal vein; GB, gallbladder. **B.** Axial anatomy, level A. The RHV, MHV, and LHV drain into the IVC. The RHV separates the anterior segment right lobe (RAS) from the posterior segment right lobe (RPS). The MHV separates the medial segment left lobe (LMS) from the RAS. The LHV acts as a boundary between the LMS and the lateral segment left lobe (LLS) and lies in the same plane as the falciform ligament (FL). FLV, Fissure for the ligamentum venosum. Dashed lines, Segmental hepatic boundaries. **C.** Axial anatomy, level A. Axial CT. **D.** Axial anatomy, level B. At this level, the ascending portion of the LPV courses between the LLS and LMS of the left lobe. The anterior and posterior segments of the right portal vein (RPV_a, RPV_p) are bisected by the RHV. BD, Bile duct; CL, caudate lobe. **E.** Corresponding CT scan. **F.** Axial anatomy, level C. This is at the level of the horizontal portion of the RPV and its bifurcation into anterior (A) and posterior (P) branches. The RHV lies midway between the portal venous branches. The LT and FL serve as a border between the LLS and LMS.

Figure 83-6, cont'd **G.** Corresponding CT section. **H.** Axial anatomy, level D. The right and left hepatic lobes are separated by a line drawn through the IVC and the gallbladder fossa–interlobar fissure (ILF). This fissure extends superiorly from the neck of the gallbladder and is often incompletely visualized on CT. The LLS and LMS are separated by the LT. **I.** Corresponding CT scan.

Figure 83-7 Subsegmental liver anatomy: Bismuth-Couinaud nomenclature. Frontal projection. Segments II and III compose the lateral segment of the left lobe and segments IVa and IVb the medial segment. Segments V and VI compose the anterior segment of the right lobe and segments VI and VII the posterior. Segment I (the caudate lobe) is not shown.

and VIII) and the inferior segments (V and VI) lie above and below the plane of the portal vein, respectively. Segmental localization, however, is difficult in patients with variant hepatic vascular anatomy. Hepatic vein landmarks may be unreliable in patients with duplication of hepatic veins. The dorsal portion of segment IV is supplied by a branch from the right hepatic artery in 8% of subjects. Accessory portal segments with independent blood supply from the main portal vein or its right branch may be seen in 30% of subjects. Riedel's lobe is an inferiorly positioned portion of the right hepatic lobe extending below the expected confines of the liver. After segmental hepatic resection, the remaining segments hypertrophy and distort the segmental anatomy by displacing the vessels.

PORTA HEPATIS

The porta hepatis is the hilum of the liver through which the portal vein, hepatic artery, common hepatic duct, nerves, and lymphatics enter the liver (Fig. 83-9). The portal vein is the most consistent anatomic landmark. The common hepatic duct is a 3- to 5-mm thin-walled structure that lies anterior to the portal vein and lateral to the common hepatic artery.²¹⁻²³ The

Figure 83-8 Caudate lobe of the liver. **A.** Diagram depicting the relationships of the caudate lobe of the liver. The caudate lobe is wedge shaped, and its posterior border abuts the inferior vena cava (IVC). The anterior border of the caudate lobe is separated from the left lobe of the liver by the fissure for the ligamentum venosum (FLV). The inferior margin of the caudate lobe forms the superior margin of the foramen of Winslow, which leads to the lesser sac. The superior margin of the caudate lobe is the cephalic portion of the right hepatic lobe, where the middle hepatic vein (MHV) enters the IVC. This corresponds to the level of the esophagogastric junction (EGJ). **B.** Schematic representation of the caudate lobe view frontally. The right margin of the caudate lobe connects to the right hepatic lobe by an isthmus. Its anterior border is formed by the fissure of the ligament venosum. The papillary process projects from the caudal margin of the caudate lobe. R, Right; L, left. (A and B from Dodds WJ, Erickson SJ, Taylor AJ, et al: Caudate lobe of the liver: Anatomy, embryology, and pathology. *AJR Am J Roentgenol* 154:87–93, 1990. © by American Roentgen Ray Society.)

Figure 83-9 Porta hepatis. Oblique sagittal sonogram demonstrates a branch of the portal vein (PV), common hepatic duct (CHD), hepatic artery (HA), inferior vena cava (IVC), and right renal artery (RRA).

right hepatic artery lies posterior to the common hepatic duct in 75% of patients and anterior in 25% of patients.

BILE DUCTS

The segmental distribution of bile ducts closely follows the course of hepatic arterial branches (Fig. 83-10A). The ducts draining the right and left lobes communicate only at the porta hepatis. There is no communication between the bile ducts of the anterior and posterior segments of the right lobe.²⁴

HEPATIC LYMPHATICS

Superficial lymphatics originate from subperitoneal tissue of the liver surface. The visceral surface drains into lymph nodes at the porta hepatis. The diaphragmatic surface drains toward the IVC and aortic lymph nodes near the celiac axis

(Fig. 83-10B). Some lymphatics penetrate the diaphragm to enter retrosternal, cardiohepatic nodes that ascend as high as the neck along the right thoracic artery.² The deep lymphatics of the liver form a major and a smaller trunk. The major trunk passes through the porta hepatis nodes, through the cisterna chyli, and, finally, into the thoracic duct. The smaller trunk courses along with hepatic veins and terminates in lymph nodes near the IVC. Lymphatics of the liver dilate secondary to cirrhosis, portal hypertension, veno-occlusive disease, right-sided heart failure, pericardial effusion, hypoproteinemia, liver transplant rejection, and glycogenesis.²

NERVE SUPPLY

The anterior hepatic nerve plexus surrounds the hepatic artery. It consists primarily of branches of the left celiac plexus, the right and left vagus nerves, and the right phrenic nerve. The posterior hepatic nerve plexus is located around the portal vein and the bile ducts. The hepatic arteries are innervated by the sympathetic nervous system. Pain from the gallbladder and the liver capsule may be referred to the right shoulder by the third and fourth cervical nerves.^{2,25,26}

Radiologic Techniques

PLAIN RADIOGRAPHY

Plain abdominal radiography has a limited role in the evaluation of the liver, both grossly and for focal lesions, because of the homogeneous soft tissue density of the liver.^{27–29} The superior border of the liver is outlined by the lung and the diaphragm. Other borders are seen only if they are outlined by intra-abdominal fat, gas-filled bowel loops, or free air. The lateral border of the liver is outlined by extraperitoneal fat continuous within the posterior pararenal space. This fat is also interposed between the inferior surface of the right hemidiaphragm and the parietal peritoneum. It may appear as a thick black line between the diaphragm and the hepatic dome radiographically.^{27,28,30} Retroperitoneal fat in the anterior pararenal space outlines the posteroinferior margin of the liver. Fluid in

Figure 83-10 Hepatic bile ducts and lymphatics. **A.** Usual branching pattern of bile ducts (green), hepatic artery (red), and portal vein (blue). **B.** Diagram depicting the lymphatic drainage of the liver. (**B** from Woodburne RT, Burkell WE: *Essentials of Human Anatomy*. New York, Oxford University Press, 1988, pp 461 and 466.)

Morison's pouch may obscure this interface, resulting in non-visualization of the edge of the liver. The anteroinferior liver edge is less commonly seen because the amount of omental and pericolic fat that outlines the margin is more variable.³¹ The left hepatic lobe extends to the left of midline, ventral to the stomach and superior to the transverse colon.

Radiographic estimation of liver size is highly unreliable because of inconsistent visualization of borders, although it is more accurate than clinical palpation.³² Radiography may aid

in detection of portal or hepatic venous and biliary tract air or calcified liver lesions, although sensitivity for these indications remains low.^{30,33} Plain abdominal radiography has become obsolete for evaluation of liver lesions with the advent and availability of cross-sectional imaging modalities like magnetic resonance imaging (MRI), computed tomography (CT), and ultrasound.

ULTRASOUND

The liver has a broad area of contact with the abdominal wall, making it an ideal organ for evaluation with real-time ultrasonography. Sonography is a safe, noninvasive, quick, and relatively inexpensive means of evaluating the liver and can be performed at the bedside, requiring little cooperation of the patient.

Evaluation Techniques

The liver is ideally examined after a 6-hour fast so that the gallbladder is not contracted. The highest possible transducer frequency should be chosen while maintaining the penetration through the posterior aspect of the liver. Near and far gain settings should be adjusted for uniform representation of echotexture of the liver parenchyma.³⁴ A small footprint transducer may improve visualization of liver for an intercostal approach. Both supine and right anterior oblique views with the patient rotated on the left side should be used. Breath hold after deep inspiration causes caudal displacement of the liver and improves the visualization of the dome of the liver. Sagittal, transverse, coronal, and subcostal oblique views complete the examination. Focal lesions are easily identified on the real-time study and may be less well appreciated on the hard copy films or static images.³⁵⁻³⁹

Sonography is an excellent modality for evaluating the course of the hepatic and portal veins. The portal vein divides at the porta hepatis into the right and left main branches. The portal veins are anechoic structures with echogenic walls. The bile ducts run with the portal veins and are too small to be seen except at the hilum, unless they are dilated.⁴⁰ Contrary to common belief, there is no constant anteroposterior relationship between the intrahepatic bile ducts and the corresponding portal veins. The hepatic arteries also run with these structures but are usually too small to be seen except with the aid of color flow Doppler imaging.⁴¹⁻⁴⁵

The hepatic veins course posteriorly and superiorly through the liver to the IVC. They are intersegmental, whereas portal veins are intrasegmental with the exception of the ascending segment of the left portal vein. The walls of the hepatic veins are usually less echogenic than those of the portal veins.

Size and Architecture

Ultrasound of the liver is commonly used for evaluation of size of the liver. However, no single measurement of the liver reflects true size because of its variable shape.^{46,47} On longitudinal scans obtained through the midhepatic line, if the liver measures 13 cm or less, it is normal in 93% of individuals. If this measurement is 15.5 cm or more, the liver is enlarged in 75% of cases.⁴⁸ Liver size should be evaluated in at least two planes to compensate for variable hepatic configuration. In the midclavicular line, the normal liver measures 10.5 ± 1.5 cm in longitudinal diameter and 8.1 ± 1.9 cm in the anteroposterior projection, with 12.6 cm and 11.3 cm being the 95th percentile.

In the midline, the normal liver measures 8.3 ± 1.7 cm (95th percentile = 10.9 cm) and 5.7 ± 1.5 cm (95th percentile = 8.2 cm) in longitudinal and anteroposterior dimensions.⁴⁹ Subjective evaluation of the configuration of the inferior border of the liver can be used to predict liver enlargement.³⁹ An inferior angle of more than 45 degrees in the left lobe and more than 90 degrees in the right lobe indicates hepatic enlargement. When the liver is enlarged, its area of contact with the anterior border of the right kidney extends below the superior two thirds of the right kidney.

The normal liver is homogeneous with fine echoes that appear as moderately small dots or lines.^{50,51} The liver has an even brightness and texture interrupted only by the hepatic veins, portal vein, and fissures. The echogenicity of hepatic parenchyma depends on the equipment, transducer, and gain settings. Hence, the parenchymal echogenicity is judged by comparison with internal references. The right renal cortex, body of the pancreas, and portal vein walls are used for internal reference. The liver is either minimally hyperechoic or isoechoic compared with the adjacent normal right renal cortex in parasagittal or lateral coronal scans (Fig. 83-11A). Compared with the liver, the pancreas is hypoechoic in the young, isoechoic in adults, and hyperechoic in the elderly because of increasing fatty infiltration of the pancreas with age (Fig. 83-11B). The liver is hypoechoic to the spleen. The lateral segment of the left hepatic lobe may extend to the left and abut the spleen, mimicking a subphrenic or subcapsular splenic fluid collection (Fig. 83-11C).⁵² The portal vein wall is echogenic in the normal liver. All these architectural comparisons assume that the kidney and pancreas are normal. When these structures are diseased, internal sonographic references are less useful. In acute hepatitis, the parenchyma is hypoechoic to the right renal cortex, and the portal vein walls appear exceptionally bright.⁵³ Conversely, in

fatty infiltration and cirrhosis, the liver is markedly hyperechoic to the right renal cortex, and the portal vein walls are “silhouetted out” by the echogenic hepatic parenchyma.⁵⁴

Artifacts

Sonographic artifacts observed in the liver can mimic abnormalities.⁵⁵⁻⁶⁰ Focal fatty infiltration and focal fat sparing of the liver can appear as hyperechoic and hypoechoic pseudolesions, respectively. These lesions commonly involve the periportal region of the medial segment of the left lobe. Focal subcapsular fat infiltration may occur in diabetic patients treated with insulin in the intraperitoneal dialysate.⁶¹ The caudate lobe may appear as a hypoechoic mass because of attenuation of the sound beam by the fissure for the ligamentum venosum. The ligamentum teres, surrounded by collagen and fat of the falciform ligament, can simulate an echogenic mass. However, this can be recognized by its typical location. Ascites can increase sound transmission to a nodular portion of the liver, simulating an echogenic mass. Accessory fissures and folding of the diaphragm into the liver can also cause echogenic pseudolesions.⁵⁵⁻⁶⁰

Intraoperative Ultrasound

Transabdominal ultrasound of the liver is limited by scattering and attenuation of the sound beam by subcutaneous fat and bowel gas. A high-frequency probe directly placed on the liver surface is without any beam scattering interfaces. Hence, with intraoperative ultrasound, high-resolution images of the liver can be obtained. Intraoperative ultrasound is an expanding field that can provide critical information to the surgeon and enable the surgeon to choose the appropriate surgical technique. The examination should be tailored to the specific needs of the surgeon to avoid undue prolongation of total duration

Figure 83-11 Echogenicity of the normal liver compared with internal standards.

A. Longitudinal scan of the right upper quadrant shows that the liver (L) is more echogenic than the right kidney (K). **B.** Longitudinal scan of the left upper quadrant in a patient with a lateral segment of the left lobe of the liver (LL) that extends to the left lateral abdominal wall shows normal liver less echogenic than spleen (S). The liver contains a small hemangioma (arrow). H, Superior; F, inferior. **C.** Transverse scan of the epigastrium shows that normal pancreas (P) is more echogenic than liver (LL). A, Superior mesenteric artery; V, superior mesenteric vein; GDA, gastroduodenal artery; Ao, aorta.

of the surgical procedure. Intraoperative ultrasound can be performed during open laparotomy as well as during laparoscopy. Small, superficially focused, high-frequency, linear array transducers are used for ultrasound during laparotomy. These transducers have a wide field of view in the near field with improved near-field resolution. Intraoperative ultrasound can be employed for diagnostic evaluation as well as for imaging guidance for intraoperative ablation of focal hepatic masses (Fig. 83-12).⁶²⁻⁷⁰

The most common application of intraoperative ultrasound is during surgery in patients undergoing segmental resection for hepatic metastases from colorectal carcinoma. Intraoperative ultrasound can provide information about the relationship of normal vascular anatomy to pathologic masses, vascular invasion or thrombosis caused by tumors, and small, nonpalpable lesions that are difficult to detect on preoperative imaging studies.^{63,70} Intraoperative ultrasound can accurately detect cysts as small as 1 to 3 mm and solid focal lesions of 3 to 5 mm. Brower and colleagues reported that the sensitivity, specificity, and accuracy of intraoperative ultrasound (78%, 100%, and 84%, respectively) are superior to those of arteriography, CT, preoperative ultrasound, and palpation for detection of liver lesions.⁷¹

Intraoperative ultrasound can detect additional liver lesions and modify the surgical management of patients with liver metastases from colorectal carcinoma.^{72,73} Intraoperative ultrasound has also been extended to use in identifying primary hepatic tumors during resection, in particular, hepatocellular carcinoma.⁷⁴ Multiple studies have now shown that intraoperative ultrasound has increased sensitivity for detection of lesions compared with contrast-enhanced CT and MRI.^{61,75-77} Some have even advocated for intraoperative ultrasound as an imaging “gold standard” for focal hepatic lesion detection.⁷⁸ Intraoperative ultrasound can be used to guide interstitial radiotherapy and cryotherapy for the treatment of liver metastases.⁷⁹⁻⁸¹ The combination of intraoperative ultrasound and ultrasound contrast agents has also been shown to increase sensitivity for

metastases not otherwise seen on preoperative CT or MRI.⁸²⁻⁸⁵ One study showed that the operative course of more than a quarter of patients was changed because of additional findings with intraoperative ultrasound.⁸⁶ The combination, however, of preoperative imaging and intraoperative ultrasound remains of highest detection value.⁸⁷

During laparoscopic ultrasound, the transducer is introduced through the laparoscopic port, usually periumbilical or right lower quadrant. A multifrequency 5-, 6.5-, or 7.5-MHz curvilinear laparoscopic ultrasound probe with a flexible tip is used. A substantial pitfall in visualization during laparoscopic ultrasound has been poor near-field visualization. Laparoscopic ultrasound can demonstrate more liver lesions compared with CT⁸⁸ and CT portography.⁸⁹ Laparoscopic ultrasound identified liver tumors not seen at laparoscopy in 33% and provided additional staging information to laparoscopy alone in 42% in a study of patients with potentially resectable liver lesions by preoperative imaging.⁹⁰

Doppler Ultrasound

Duplex and color flow Doppler imaging improve the diagnostic capabilities of ultrasound by enabling the evaluation of complex circulatory dynamics of the liver.^{33,91-96} Thrombosis, reversal of flow, aneurysms, and fistulas are better demonstrated with duplex and color flow Doppler sonography than with gray-scale ultrasound.^{33,92,96,97} Doppler settings need to be optimized to achieve the greatest sensitivity to allow the detection of low flow, and power Doppler may be helpful in this setting. Color gain must be increased to a level just below the level that would create artifacts. In addition, Doppler imaging can be used for detection of vascularity and vascular invasion of focal lesions of the liver. Color and spectral Doppler are unable to detect the vascularity of the majority of focal lesions of the liver because of low intensity of the signals. Tumor vascularity is better evaluated with power Doppler and ultrasound contrast agents.

Doppler tracing of the hepatic artery demonstrates a high diastolic flow that indicates low impedance (Fig. 83-13A).

Figure 83-12 Hepatocellular carcinoma: intraoperative ultrasound and CT. **A.** CT demonstrates a low-attenuation lesion (arrows) adjacent to combined confluence of left and middle hepatic veins. **B.** Sagittal ultrasound image during laparotomy confirms that the lesion (arrows) cannot be resected free of the left hepatic vein (LHV). (Courtesy Helena Gabriel, MD, Chicago, IL.)

Figure 83-13 Normal duplex Doppler sonography of the hepatic vessels. **A.** The normal hepatic vein has a complex triphasic waveform because of the combination of regurgitation of blood from the right atrium associated with atrial systole and variations of intra-abdominal pressure associated with respiration. **B.** The normal portal vein has a characteristic continuous flow pattern that is modulated by respiratory variation. **C.** The normal hepatic artery demonstrates forward flow throughout diastole. The amount of diastolic flow varies with fasting status.

Doppler sonography is most often used to differentiate the hepatic artery from a bile duct in the porta hepatis. Color flow images may be needed to localize the hepatic artery.⁹⁸ The intrahepatic branches of the hepatic artery are usually not visualized on gray-scale ultrasound. When there is compensatory dilation of intrahepatic branches of the hepatic artery in cirrhosis, Doppler ultrasound can differentiate this from dilation of intrahepatic biliary radicals.

In liver transplant recipients, survival of the allograft depends on patency of the hepatic artery. Changes in the normal hepatic artery waveform may suggest stenosis or thrombosis in these patients.^{99,100} These changes include slow rise to peak systole, diminished amplitude, and prominent diastolic flow, referred to as a *tardus-parvus* waveform. The normal marked increase in postprandial hepatic artery resistive index seen in normal individuals is generally not seen with severe liver disease.¹⁰¹

The flow pattern of the hepatic veins (Fig. 83-13B) is similar to that of the IVC and other large systemic veins, undulating with cardiac and respiratory motion. Normal hepatic venous flow is directed toward the vena cava. With tricuspid regurgitation, there is a pronounced systolic reversal of hepatic venous blood flow.¹⁰² The triphasic pattern is lost in cirrhosis as the liver, which encases the hepatic veins, becomes less compliant.¹⁰³

The portal vein has a characteristic continuous flow pattern (Fig. 83-13C) modulated by respiratory variations. This normal

respiratory variation is either attenuated or lost in portal hypertension.¹⁰³ Portal vein pulsatility is increased in patients with right-sided heart failure, as cardiac pulsations are transmitted to the portal vein.

Tissue Harmonic Imaging

Conventional gray-scale ultrasound transmits and receives the sound beam at the same frequency. In tissue harmonic imaging (THI), the second harmonic signal is received by filtering out the fundamental echoes from the tissue being evaluated. Body wall artifacts, side lobes, and scatter are minimized and signal-to-noise ratio is improved with THI as the harmonic signals are generated in the tissues.¹⁰⁴ The shorter wavelength of the sound beam used in THI results in improved axial resolution. THI can detect additional liver lesions and alter the clinical management compared with conventional ultrasound.¹⁰⁵

Ultrasound Contrast Agents

The availability of ultrasound contrast agents has extended the clinical applications of sonography to primarily aid in the display of parenchymal microvasculature.¹⁰⁶ An ultrasound contrast agent is defined as an exogenous substance that can be administered either in the blood pool or in a cavity to enhance sonographic signals. Contrast agents increase the backscattered signal intensity, resulting in improved gray-scale echogenicity on sequences such as harmonic imaging and pulse inversion as

well as increased color and spectral Doppler signal strength. Agents are injected intravenously, and imaging proceeds immediately thereafter. The advantages of contrast-enhanced ultrasound are the ability to assess contrast enhancement in real time and the excellent temporal resolution. Contrast agents generally also have a strong safety profile. The limitations of contrast-enhanced ultrasound include a relatively narrow time window available for scanning after administration of the contrast agent and limited evaluation if the baseline ultrasound is also limited.

Ultrasound contrast agents for evaluation of the liver are microbubbles stabilized by a shell. The most prevalently used include SonoVue (Bracco SpA, Milan, Italy), a sulfur hexafluoride encased in a phospholipid shell, introduced in 2001 and available in Europe, China, India, Korea, Hong Kong, New Zealand, Singapore, and Brazil; Definity (Lantheus Medical, Billerica, MA), a perflutren in a lipid shell, introduced in 2001 and available in Canada and Australia; Sonazoid (Daiichi-Sankyo, GE, Tokyo, Japan), a perfluorobutane in a phospholipid shell, introduced in 2007 and available in Japan and South Korea; and Levovist (Bayer Schering AG, Germany), a granule of galactose and palmitic acid, for which production is halted.¹⁰⁶ At the time of this writing, none of these agents or any ultrasound contrast agent has been approved by the Food and Drug Administration for clinical use in the United States.

Most agents have similar vascular behavior, with rapid enhancement of the vasculature after injection and slow dissipation during 5 to 10 minutes. Sonazoid is an exception and has an extended late phase, known as the post-vascular phase, and can persist up to a couple of hours in the liver because of phagocytosis by Kupffer cells.^{107,108}

Harmonic imaging detects microbubbles as they resonate at their characteristic frequencies. Microbubble contrast agents are better demonstrated and detected longer in various organs as well as in tumor vessels with harmonic imaging than with color Doppler imaging.¹⁰⁹ Quaia and associates¹¹⁰ reported that pulse inversion harmonic imaging with ultrasound contrast agents detected additional liver metastases in 47% of patients compared with conventional gray-scale ultrasound. Liver metastases even as small as 2 mm can be detected by pulse inversion harmonic imaging with ultrasound contrast enhancement.¹¹¹ Tissue canceling ultrasound techniques can provide a microbubble-only image that can be helpful for making lesions more prominent than by superimposition of microbubble and B-mode images; however, users must be careful about understanding unique artifacts in this mode.¹¹²

Ultrasound contrast agents generally have a good safety profile. Unlike with CT and MR agents, there is no associated known nephrotoxicity. The risk of severe allergic and anaphylactic response is similarly low to that of MR contrast agents.¹¹³ Although the risks are low, emergency response and a trained clinician should be immediately available, just as with all administrations of contrast agents.

COMPUTED TOMOGRAPHY

Advances in multidetector CT (MDCT) technology have revolutionized liver imaging. MDCT enables fast scan coverage and acquisition of submillimeter section thickness images of isotropic volume resolution. Faster image acquisition enables multiphasic CT acquisition through the liver with injection of a single bolus of contrast material, and the isotropic image data set improves the conspicuity of small lesions and the quality of

three-dimensional (3D) reformations.¹¹⁴⁻¹¹⁷ The multiplanar reformations can better demonstrate the anatomic relationship of hepatic focal lesions with the blood vessels, which can help surgeons plan segmental resection of the liver. The 3D reformations enable illustration of hepatic vascular anatomy for evaluation of liver donors. Emerging techniques like dual-energy CT (DECT) and CT perfusion imaging have added new horizons of capabilities to CT with lesion detection, characterization, and treatment monitoring.

Unenhanced Computed Tomography

Noncontrast CT scans of the liver are inferior to contrast-enhanced studies for lesion detection and thus are not routinely performed except in certain specific situations.¹¹⁸⁻¹²⁰ Liver disorders that diffusely alter hepatic attenuation, such as fatty change, hemochromatosis, glycogen storage diseases, chemotherapy, amiodarone administration, and gold therapy, should be evaluated with noncontrast CT. Patients with cirrhosis should also undergo noncontrast scans to search for iron in dysplastic and siderotic nodules. Noncontrast liver CT may be indicated for evaluation of lesion calcification, hemorrhage (in lesions like hepatocellular adenomas; Fig. 83-14), and metastases from hypervascular tumors like carcinoid, renal, thyroid, insulinoma, pheochromocytoma, and breast.¹²¹⁻¹²⁴ These hypervascular metastases may become isodense after contrast enhancement.^{125,126} However, DECT with the capability to reconstruct virtual unenhanced images similar to true noncontrast CT can preclude acquisition of separate noncontrast series as further discussed later.¹²⁷

Contrast-Enhanced Computed Tomography

Iodinated Contrast Dynamics. The goal of contrast enhancement is to improve lesion visibility by increasing the relative attenuation difference between the lesion and normal hepatic parenchyma. This difference is a fundamental factor in lesion conspicuity and characterization.¹²³ Many factors affect the timing and degree of hepatic enhancement and thus the contrast difference between normal hepatic parenchyma and lesions. Hepatic enhancement is most dependent on the phase

Figure 83-14 Hemorrhage in hepatocellular adenoma. Noncontrast CT of upper abdomen of a 28-year-old woman with hepatocellular adenoma reveals a central hyperdense area (arrow) within the hypodense mass suggestive of hemorrhage.

of the contrast delivery during which scanning occurs. These phases can be divided into vascular, redistribution, and equilibrium.¹²⁸ During the vascular phase, there is a rapid increase in aortic enhancement and a slow increase in hepatic enhancement. This phase is short because iodinated contrast material diffuses rapidly from the vascular blood pool to the extravascular or interstitial space of the liver, thus beginning the redistribution phase. During this time, there is a rapid decrease in aortic enhancement and an increase in hepatic enhancement. This represents the ideal time for detecting most lesions (Fig. 83-15). In the equilibrium phase, there is decline in aortic and hepatic enhancement. Hence, lesions may become isoattenuating to hepatic parenchyma.

Helical CT technology allows multiphase CT acquisition with the administration of a single bolus of contrast material. An initial acquisition can be obtained during the hepatic arterial phase, so that highly vascular lesions are highlighted against a background of nonenhanced normal liver parenchyma. These lesions may become isodense with remaining liver if scanning is performed later. A later, portal venous (redistribution) phase scan is obtained when most of the contrast material bolus enhances the normal hepatic parenchyma. Because metastases receive primarily arterial blood supply, most metastases are hypodense compared with normal liver (see Fig. 83-15). These phases are further discussed in the section on biphasic scanning.

The timing of these different phases and peak enhancement is directly affected by the way in which contrast material is delivered. The volume, type, concentration, and rate of injection of contrast material used affect the time to peak enhancement. Several studies suggest that the time to peak contrast enhancement is dependent on the duration of contrast material injection.¹²⁹⁻¹³¹ Higher injection rate or lower volume injections produce an earlier peak enhancement because of the short duration of the injection.

The amount of hepatic enhancement is determined by technical and patient-related factors. Technical factors include concentration of the contrast material, volume, and injection rate. These factors have interdependent effects.¹²⁹ Hepatic enhancement increases with higher volume, injection rate, and concentration of the contrast material.¹³²⁻¹³⁸ Increasing the injection rate from 2 to 3 mL/s results in 16% increase in peak hepatic enhancement.¹³⁹ However, increasing the injection rate above 4

to 5 mL/s does not result in substantial increase in peak hepatic enhancement.¹⁴⁰

Patient-related factors that affect enhancement include weight and cardiac output. There is decreasing hepatic enhancement with increasing weight.¹³⁰ In thin patients undergoing spiral CT, the dose of the contrast agent may be reduced by up to 40%.¹³⁶ Megibow and associates¹³⁴ reported that a weight-based dose of 1.5 mL/kg of 300 mg I/mL contrast material can provide acceptable contrast enhancement in most patients, with a significant cost savings. Although faster image acquisition with MDCT has enabled considerable reduction of the dose of the contrast agent for CT angiography studies,¹⁴¹ enthusiastic reduction of the contrast material dose for CT evaluation of the liver is limited by the minimum iodine dose required for optimum liver enhancement. The iodine dose required to achieve a hepatic enhancement of 50 HU has been reported to be 521 mg I/mL.^{142,143} Decreased cardiac output delays hepatic enhancement.

Faster image acquisition with MDCT mandates high iodine influx rate for optimum enhancement. High-concentration contrast material is a valuable option for this because of the limited range of possible fast injection rates. Increased enhancement of hepatocellular carcinoma in arterial phase CT and improved lesion conspicuity with high-concentration contrast material (370 mg I/mL) have been reported.¹⁴⁴ This improved enhancement with high-concentration contrast material is visually significant in patients weighing more than 65 kg.¹⁴⁵ The use of a chaser bolus of 20 mL of saline has been reported to increase the enhancement of liver, portal vein, and aorta.¹⁴⁶

Automated methods of timing delivery of the contrast material have been advocated to achieve a greater and more consistent level of hepatic enhancement from patient to patient than with the use of a conventional fixed delay time.^{147,148} These methods make use of a region of interest placed on the aorta, portal vein, or liver parenchyma. During delivery of the contrast material, multiple images are obtained at a fixed level at 3- to 5-second intervals. When a preselected threshold of 50 HU is reached, the scan is initiated.¹⁴⁹ Automated bolus tracking can increase the mean liver parenchymal enhancement substantially compared with empirical time delay scanning.¹⁵⁰⁻¹⁵² In addition, automated bolus tracking can improve the liver-to-lesion conspicuity.¹⁵³

Figure 83-15 Importance of timing of contrast material bolus in liver lesion detection on CT. To evaluate a possible pancreatic mass, a thin-collimation spiral was obtained from the inferior pancreas upward, with a second spiral covering the cranial portion of the liver. Although present on subsequent ultrasound, no metastases were detected on the lower image (A) because scanning occurred during the arterial phase. The more cranial portal venous phase image (B) demonstrates multiple metastases (arrows) from a nonhypervascular carcinoid tumor.

Helical Portal Venous Phase Scan (Single-Phase Scan). This is the preferred CT technique for routine hepatic evaluation. With helical CT, the entire liver can be scanned during peak parenchymal enhancement, further improving diagnostic accuracy.¹⁵⁴ This is accomplished by imaging the liver beginning at about 55 to 70 seconds after the start of the contrast material bolus, depending on injection rate. Reduced cardiac output can delay the peak hepatic enhancement. Most centers use 100 to 150 mL of 300 to 370 mg I/mL contrast material injected at a rate of 3 mL/s or more.

Biphasic Helical Scan. Biphasic CT using a hepatic artery dominant phase technique and a portal venous phase technique is more efficacious than conventional CT using a single portal venous phase technique to detect hypervascular lesions, including hepatocellular carcinoma and metastases from renal, breast, carcinoid, and pancreatic islet cell tumors. Attenuation differences between an intensely enhancing hypervascular metastasis supplied by hepatic arterial flow and the remainder of the liver are maximized during the arterial phase scan (Fig. 83-16A). Portal vein flow would render the hypervascular metastases isoattenuating (Fig. 83-16B). Arterial phase images are acquired by scanning 20 to 30 seconds after the start of injection of the contrast material. The time at onset of arterial phase is dependent on the injection rate of the contrast material.¹⁵⁵ With a fixed injection rate, small changes in volume do not affect the duration of the arterial phase.¹⁵⁶ Faster injection rates increase the amount of arterial enhancement as well as the length of time between peak aortic enhancement and the end of the arterial phase, which might increase detection of hypervascular tumors.¹⁵⁵ A second acquisition is then obtained during the portal venous phase, after a delay of 55 to 65 seconds from the

beginning of the injection of the contrast material. Contrast material is delivered at a faster rate of 4 to 5 mL/s for biphasic CT study, instead of 3 mL/s, which is used for single-phase CT study.

Biphasic helical scanning has been found especially helpful in hepatocellular carcinoma, in which the addition of an arterial phase scan improves lesion detection compared with portal phase scans alone or CT arterial portography.¹⁵⁷⁻¹⁵⁹ In addition, arterial phase data enable vascular road mapping for oncologic liver surgery planning.¹⁶⁰ Detection of a hypervascular hepatic lesion in a patient with cirrhosis is suggestive of hepatocellular carcinoma. Biphasic technique for the detection of hypervascular metastases has had more mixed results. Several studies have found that 21% to 37% of lesions 2 cm or smaller either are visible only or are more conspicuous on arterial phase images.^{161,162} Another study, however, found that nonenhanced and portal venous phase images detected significantly more hypervascular metastases than did hepatic arterial phase and portal venous phase or portal venous phase images alone.¹⁶³ Hepatic arterial phase scanning does not need to be performed for evaluation of hypovascular hepatic lesions as they do not show enhancement during the hepatic arterial phase.¹⁶⁴ Although multiphase liver imaging with MDCT improves sensitivity and specificity of liver imaging, the risk of radiation exposure increases with this.¹⁶⁵ Application of automatic exposure control may result in substantial reduction of radiation dose to the patient while maintaining acceptable image quality.^{166,167}

Delayed Iodine Scanning. Delayed scanning has been employed to improve detection of intrahepatic cholangiocarcinoma (Fig. 83-17) and metastases.¹⁶⁸⁻¹⁷³ Cholangiocarcinoma

Figure 83-16 Hypervascular metastases: biphasic CT demonstrating carcinoid metastases only on arterial phase images. Arterial phase CT image (A) demonstrates multiple brightly enhancing metastases that are invisible on portal venous phase scan (B). Images are displayed at narrow (liver) windows.

Figure 83-17 Delayed enhancement of hilar cholangiocarcinoma. Portal venous phase CT image (A) of 55-year-old woman with hilar cholangiocarcinoma causing biliary obstruction demonstrates isodense mass (arrow) at porta hepatis with intrahepatic biliary dilation. Delayed image (B) obtained after 10 minutes reveals enhancement of this mass (arrow). Images are displayed at narrow (liver) windows.

appears hyperdense on delayed scans in 74% of patients.¹⁶⁸ Studies assessing whether delayed scanning is helpful in detecting hepatocellular carcinoma have produced conflicting results.^{157,159} In one study, the sensitivity of detection of hepatocellular carcinoma increased by 4% by addition of delayed phase scanning (180 seconds) to the hepatic arterial and portal venous phase scanning.¹⁷⁴ In addition, the filling in of hemangioma with contrast material can be demonstrated on delay phase scans.

Computed Tomography Angiography and Portography. In this technique, an arterial catheter is placed selectively in the hepatic, splenic, or superior mesenteric artery in the angiography suite and contrast material is injected through this catheter.^{123,175,176} Hence, during CT arterial portography (CTAP), there is dense enhancement of liver parenchyma receiving portal venous blood.¹⁷⁷⁻¹⁷⁹ Liver lesions that receive primarily arterial rather than portal venous blood supply appear as hypodense defects on CTAP.^{176,177,180}

Perfusion defects and other artifacts diminish the specificity of CTAP.^{181,182} CTAP has a false-positive rate of 15% to 17%.¹⁸³ An additional delayed phase acquisition can improve the specificity of CTAP.¹⁸⁴ CTAP is seldom performed now because of its invasive nature and increasing use of noncatheter CT angiography and intraoperative ultrasound.

Computed Tomography Liver Protocol Optimization and Radiation Dose Reduction

Protocol Optimization. When it is necessary to perform CT, the radiologist should aim to reduce the CT dose but yet maintain diagnostic image quality. To achieve this, the single most important step is protocol optimization. Optimization of CT technique involves careful selection of scan length and manipulation of several modifiable parameters during the scan, including slice thickness, pitch, tube current, peak tube potential, gantry rotation speed, and noise reduction reconstruction algorithms.

Adjustments to tube current and peak tube potential are among the most common strategies in optimizing CT protocol. Tube potential should be optimized more carefully because unlike tube current, it affects not only the image noise but also the tissue contrast. For a given image noise, higher peak kilovoltage techniques require lower tube current and vice versa. The patient's size should serve as an appropriate guide. Most routine adult abdomen CTs performed at 120 kVp rather than at 140 kVp achieve 20% to 40% reduction in radiation dose. For patients with a larger body habitus, however, 140 kVp tube potential should be employed to avoid loss of diagnostic quality. For smaller subjects, such as pediatric patients, peak kilovoltage may be decreased to 100 or 80 as smaller body habitus leads to minimal attenuation of the x-ray beam, allowing adequate image quality without significant increase in tube currents. A low peak kilovoltage approach at 100 kVp for CT hepatic angiography in organ donor patients may be used; this has been shown to achieve 30% to 35% dose reduction compared with 120 kVp, without affecting diagnostic quality¹⁸⁵⁻¹⁸⁷ (Fig. 83-18).

The tube current on modern CT scanners is determined by automatic modulation of tube current (ATCM). Many studies have shown that ATCM can significantly decrease radiation dose. The basic principle behind the ATCM techniques is to customize the tube current on the basis of the patient's thickness along the z-axis or axial plane derived by orthogonal scout

Figure 83-18 CT angiogram of a liver donor patient (body weight, 74 kg) at 100 kVp tube potential still provides good delineation of arterial mapping. Use of a low peak kilovoltage approach over the standard 120 kVp can attain dose reduction of up to 20% to 30%. RHA, Right hepatic artery; SMA, superior mesenteric artery.

projections. This reduces the radiation dose compared with a fixed tube current across the entire rotation. ATCM relies on user-specified image quality in terms of image noise or tube current–time product value. In scanning younger patients, particularly children, lower tube currents with radiation doses as low as reasonably achievable and lower than those for most adult patients should be employed. One may also consider lower fixed tube current settings, based on patient weight or body girth. Because there is wide variation in weight, varying from less than 5 kg up to 100 kg, selection of tube current as well as peak tube potential factors should be carefully done by categorizing into different weight groups. A prospective study exhibited that a mean dose reduction in the abdomen and liver of 38% with angular modulation and 18% with z-axis modulation can be achieved with no compromise in image noise or quality. The selection of image noise level is based on the clinical indication of the liver CT. For example, CT angiography should be undertaken at a relatively higher image noise level compared with portal phase CT for detection of low-contrast liver metastases. Automatic selection of peak tube potential, which functions on the basis of the patient's tissue attenuation profile, has also been implemented recently.¹⁸⁶⁻¹⁹²

Although it is possible to achieve submillimeter imaging on current MDCT scanners, thinner slice images require an increase in radiation dose to maintain an adequate signal-to-noise ratio. In clinical practice, typically 2.5- to 5-mm prospective slices are reconstructed. When thinner slice images are required, for example, in hepatic CT angiography requiring 1-mm slice especially for 3D reconstruction, a reasonable approach would be to obtain thicker slice images but then to retrospectively reconstruct at the desired thickness from the volumetric data. This is a feature that is available on most modern MDCT scanners.¹⁹³

Keeping other CT parameters constant, faster table speed, for a given collimation, results in higher pitch with reduced

Figure 83-19 **A.** Coronal CT images of 56-year-old patient (body weight, 91 kg) with routine contrast-enhanced CT in portal venous phase (120 kVp; noise index, 15; automatic tube current, 150-550 mA) performed with filtered back projection technique shows increased image noise and artifact. **B.** In the same patient, CT done at different time point using ASIR reconstruction (120 kVp; noise index, 19; automatic tube current, 150-450 mA) shows improved image noise and image quality and substantially reduced artifacts.

radiation dose and vice versa. Modern MDCT scanners have mechanisms to automatically recommend the appropriate tube current to maintain a given image noise level when the pitch is changed. A pitch factor of approximately 1.0 to 1.3 can be used for CT of the abdomen and pelvis in patients weighing up to 300 pounds and a lower pitch of 0.7 for large patients (>300 pounds). Higher pitches should be avoided because they are associated with worsening helical artifacts and may also potentially miss some data.^{188,194}

Noise Reduction Techniques. Filtered back projection algorithms are inherently sensitive to low-dose examinations, resulting in increased image noise. Image noise reduction algorithms include conventional noise reduction filters and newer techniques based on iterative reconstruction. These techniques primarily do not decrease radiation dose but enhance image quality by decreasing image noise and improving contrast from low-dose CT. On the other hand, noise reduction filters, popularly the adaptive CT filters using linear processing techniques, result in homogeneous decrease in image noise across all pixels, thereby reducing image contrast and conspicuity of smaller lesions. This potential drawback limits the dose-saving capability of CT image filters.^{195,196}

By using nonlinear processing, iterative reconstruction techniques have been able to avoid an unacceptable tradeoff between image contrast/resolution and image noise, especially at substantially reduced doses. Because conventional iterative reconstruction methods required long computational times, shorter partial reconstruction algorithms applied in projection or the image space domain were initially introduced by different vendors. More recently, robust full iterative reconstruction algorithms have been made available for clinical use by different vendors. Such techniques include adaptive statistical iterative reconstruction (ASIR) and model-based iterative reconstruction (MBIR) by GE HealthCare and iterative reconstruction in image space (IRIS) and sinogram-affirmed iterative reconstruction (SAFIRE) by Siemens Medical Solutions. Investigators have tested and validated the utility of such techniques, which

have enabled dose reduction to as much as 40% to 60% lower than with standard-dose CT (Fig. 83-19). By synergistic use of these described strategies with noise reduction filters with iterative reconstruction methods, CT protocols at significantly lower dose can be implemented while minimizing compromising diagnostic capability.^{193,197-199}

Computed Tomography Perfusion Imaging

CT perfusion imaging is a functional tool based on temporal changes in tissue density on dynamic contrast-enhanced image acquisition. By dynamic contrast-enhanced imaging, tumor perfusion parameters can be captured and quantified by applying certain mathematical models. Owing to increasing use of targeted therapy like antiangiogenic drugs directed at tumor vascularity, perfusion imaging has received increased attention. Because of its ability to detect early changes in tumor microenvironment, which precede morphologic changes within tumor, CT perfusion is suited to monitor early effects of antiangiogenic therapies. CT perfusion has the advantage of excellent spatial resolution and simpler quantification of tissue vascularity due to a linear relationship between iodine concentration and tissue density. Improved scanner technology in current MDCT with faster scanning time and wider coverage makes this technique feasible for various abdominal applications, including evaluation of liver lesions.^{200,201}

CT perfusion technique typically involves an initial noncontrast scan to localize a lesion followed by a contrast-enhanced dynamic acquisition using 40 to 70 mL of intravenous contrast material at a rate ranging from 3.5 to 10 mL/s. Typically, a first-pass phase (usually 45-60 seconds) is followed by a delayed phase (usually 2-10 minutes) for optimal assessment of tumor perfusion and permeability measurement. Postprocessing of dynamic data is performed with perfusion software to generate color-coded maps of blood flow, blood volume, mean transit time, and surface permeability. Quantitative assessment of the lesion is performed with region-of-interest analysis. Analyzed perfusion parameters of the perfusion software may vary by commercial vendors (Fig. 83-20).

Figure 83-20 Liver metastasis. **A** and **C**. CT perfusion images before and after antiangiogenic treatment in a 53-year-old man with liver cancer (arrow). **B**. Colored perfusion map of blood flow (arrow) at baseline before antiangiogenic treatment shows a high tumor blood flow (140 mL per 100 g/min). **D**. Colored perfusion map after treatment shows a reduction in tumor blood flow (104 mL per 100 g/min). On contrast-enhanced CT images (**A** and **C**), the lesion appears stable by size.

In oncologic imaging, the role of CT perfusion has been investigated and found useful in evaluation of liver tumors. Many studies have found CT perfusion effective to characterize and to assess biologic aggressiveness of hepatocellular carcinoma and in monitoring response to treatment. In treated metastasis, higher perfusion parameters have been shown to be a good prognostic indicator suggesting desired response to treatment. Among nononcologic applications, CT perfusion can be used for quantification of liver perfusion. There is evidence that this may be helpful for earlier evaluation of liver cirrhosis.^{202,203}

Use of CT perfusion, however, is limited because of high radiation dosage and limited coverage (2–4 cm), although the latter limitation is addressed by recent improvement in technology, enabling larger coverage of up to 40 cm. Another limitation is lack of standardized guidelines on image acquisition and data analysis, thereby limiting reproducibility.

Dual-Energy Computed Tomography

DECT is an evolving modality with specific capacities beyond single-energy CT that can translate into improved liver imaging. The two different energy settings acquired allow the differentiation of materials on the basis of their energy-related attenuation characteristics and have the potential to provide better lesion detection, characterization, and monitoring than with single-energy CT. The basic concept of DECT is based on the principle that different elements absorb x-rays with different attenuation, depending on the electronic configuration of atoms.

DECT is performed with two concurrent x-ray beams at different kilovoltage peaks, usually 80 and 140 kVp, during

the same study. Depending on the vendors, different approaches are used to perform dual-energy scanning. In one design, this is achieved by mounting two x-ray tubes in the gantry that are set at different energy levels. In another design, a single x-ray tube capable of rapidly switching between differing energy levels is used. A third approach, which is yet to be commercially available, involves two layered sandwich detectors that can absorb lower and higher energy photons. The DECT technology provides advanced postprocessing applications, including virtual noncontrast (VNC), monochromatic (at different energy levels), and iodine images, which have wide potential applications.²⁰⁴

For most hepatic applications, dual-energy scanning is performed in the arterial phase at the tube potentials of 80 and 140 kVp for patients weighing less than 200 pounds and 100 and 140 kVp in patients weighing more than 200 pounds for optimal material and tissue characterization. Dual-energy imaging has been found useful to improve lesion detection and characterization. In oncology, detection and quantification of iodine can help assess tumor viability and monitor therapy response.²⁰⁵

Improved Lesion Detection. Because of the k-edge proximity, in comparison to standard 120 kVp images, increased conspicuity of hypervascular liver lesions can be attained on 80/100 kVp and low-energy monochromatic images (40–70 keV) to increase the conspicuity of enhancing lesions. Such an application can improve diagnosis and management of hepatocellular carcinoma as well as of metastasis from hyperenhancing primary tumors (e.g., renal cell carcinoma, melanoma)

(Fig. 83-21). Low-kiloelectron volt or low-energy monochromatic images can also be used for 3D vascular mapping and reconstruction in liver donor subjects.^{206,207}

Improved Characterization. DECT imaging can be used to determine presence of fat, iron, calcium, or hemorrhage within the tumor, which can help narrow a differential diagnosis. For example, detection of fat within a hepatic tumor is suggestive of adenoma or hepatocellular carcinoma, whereas calcium indicates prior infection or mucinous metastasis. It may also help in differentiating simple cysts and hypodense metastatic lesions by analyzing internal iodine uptake, which can be positive in metastasis. Currently published data on DECT for characterization of hepatic lesions have demonstrated variable results and continue to evolve.²⁰⁴ Further studies are needed for validation.

Virtual Noncontrast Imaging. VNC images reconstructed from DECT acquisition may provide information similar to that of a true noncontrast CT image. Although on first-generation DECT the VNC images were not exactly equivalent to true noncontrast CT images, several studies have confirmed that VNC images on second-generation DECT provide attenuation values close to those of true noncontrast CT and are sufficient to assess and quantify the enhancement of focal liver lesions. When contrast-enhanced phase alone is performed, VNC images may be used to distinguish calcification (e.g., mucinous metastases) from contrast enhancement. This can

obviate the need for a separate unenhanced phase, thus limiting CT phases and radiation burden to the patient.^{204,208,209}

Therapy Monitoring. Image biomarkers of tumor biology are desired for predicting response to treatment and for follow-up of lesions during and after treatment. After radiofrequency ablation and cryoablation of hepatic lesions and in patients who undergo antiangiogenic therapies, the tumor dimensions may remain stable but change in vascularity, representing the earliest marker of treatment response. Iodine images are a new method and an alternative for monitoring response to treatment. A study has shown better lesion conspicuity and internal homogeneity of the ablation zone on iodine maps, providing an additional benefit for assessing the safety margin after radiofrequency ablation²¹⁰ (Fig. 83-22).

MAGNETIC RESONANCE IMAGING

MRI allows tissue characterization without ionizing radiation. Given the proximity of the liver to the heart and lungs, a tailored protocol is required to minimize motion artifact. Only since the development of rapid acquisition techniques with excellent image quality and tissue-specific contrast agents has MRI become the most accurate imaging modality for the evaluation of liver disease.²¹¹ In many instances, with the appropriate combination of sequences, MRI can diagnose and characterize diffuse liver disease accurately and obviate the need for invasive procedures.²¹² MRI therefore plays an important role in the

Figure 83-21 **A.** Dual-energy contrast-enhanced CT in a patient with known hepatocellular carcinoma shows hypervascular lesions in the liver (arrows) on weighted 120 kVp image. **B.** However, on monochromatic spectral image at 40 keV reconstructed from the same acquisition, the same lesions (arrows) have improved conspicuity, and some additional lesions are better detected (arrowheads).

Figure 83-22 **Hepatocellular carcinoma after radiofrequency ablation.** **A.** On weighted 140 kV image, there is hyperdensity within the radiofrequency ablation bed, which may represent enhancement, suggesting local recurrence, or hemorrhage. **B.** On iodine image, there is no enhancement, confirming it to be hemorrhage, demonstrating better tissue characterization.

evaluation of complications and in the follow-up of diffuse hepatic disease, and it is an invaluable tool for characterization of focal lesions.

Many different pulse sequences can be used in hepatic MRI. Choice of sequence and performance depend on magnetic field strength, software, and gradients. The advent of 3T systems has increased available options, but more experience still exists with 1.5T magnets.

In general, T1- and T2-weighted sequences are performed, and contrast agents are added in most situations. Use of torso phased-array surface coils instead of body coils increases signal-to-noise ratio by at least a factor of 2, thereby providing increased lesion-to-liver contrast, lesion detection, and image definition.^{213,214}

T1-Weighted Sequences

The purpose of obtaining T1-weighted images is twofold. First, T1-weighted images provide basic tissue characterization, such as the detection of fat and blood products. Second, T1-weighted images are the mask to which subsequently acquired contrast-enhanced images will be compared to determine tissue enhancement characteristics.

Fast spoiled gradient-echo sequences with short repetition time and echo time and low flip angles are most frequently used to obtain T1-weighted images. Examples include fast low-angle shot (FLASH) on Siemens and spoiled gradient recalled acquisition in the steady state (GRASS, SPGR) on GE systems (Fig. 83-23).

These sequences allow imaging of the entire liver during a single 15- to 25-second breath hold, a prerequisite for dynamic contrast-enhanced imaging when the same area is acquired at multiple time points after intravenous administration of contrast material.²¹⁵⁻²²⁴

On T1-weighted images, the signal intensity of normal liver is greater than that of spleen, muscle, and kidney and less than that of surrounding fat. Bile, ascites, and fluid-filled gut have the lowest signal intensities.²²⁵ Bile within the gallbladder

may have a layering of signal intensities related to the state of fasting and relative lipid, aqueous, proteinaceous, and calcified contents.²²⁶ Most hepatic tumors and abscesses have a long T1 and thus appear as hypointense lesions on T1-weighted images. Most blood vessels appear as dark structures because of flow void phenomena.^{12,227} Portions of the hepatic or portal venous system and IVC may appear hyperintense or isointense with the liver because of inflow phenomena and even echo rephasing.²²⁸

T2-Weighted Sequences

Spin-echo, segmented spin-echo (such as fast or turbo spin-echo), and short tau inversion recovery (STIR) sequences can be used to obtain T2-like information (Fig. 83-24). When spin-echo techniques with a long repetition time (>2000 ms) and long echo time (80-120 ms) are used, T2 differences predominate^{229,230} (see Fig. 83-24). Signal intensity increases with increasing T2 values, and structures with long T2 values, such as gallbladder, fluid-filled bowel, ascites, spleen, and kidney, become bright. Fat is somewhat less bright, and liver and muscle are relatively hypointense. The lung and air-filled bowel are black.

Segmented (fast) spin-echo sequences with fat saturation are commonly used in place of conventional spin-echo images to achieve T2-weighted images. In these sequences, a series of seven or more spin echoes is typically acquired after an initial 90-degree excitation. This enables substantial scan time reduction.^{223,231,232} Fast spin-echo techniques have shown consistently sharper anatomic detail with fewer respiratory and cardiac motion artifacts than in conventional spin-echo sequences.²³³ Segmented spin-echo sequences can also be performed as a breath-hold technique to reduce motion and aortic pulsation artifacts further.²³⁴ These sequences are thought to be at least equivalent to conventional spin-echo sequences.²³⁵ Half-Fourier acquisition single-shot turbo spin-echo (HASTE) is a modification of turbo spin echo allowing a further reduction in scan time by use of a slab acquisition mode.²³⁶

Figure 83-23 Liver MRI: T1-weighted gradient-echo image. This axial T1-weighted gradient-echo image (142/4.4/80 degrees) has excellent anatomic detail. The signal intensity of the liver is greater than that of spleen and muscle. Note the peripheral bright signal intensity from the torso phased-array coil.

Figure 83-24 Liver MRI: rapid T2-weighted image. This axial T2-weighted turbo spin-echo image (2118/80 degrees) exploits differences in T2 relaxation between normal liver and masses. Spleen, kidneys, gallbladder, and bile become brightest. Liver and muscle become relatively hypointense. This image was obtained in a body coil.

STIR imaging can be performed to acquire T2-like information. These sequences suppress fat signal, relying on its short T1 relaxation time. When the TI of inversion recovery sequences is reduced to 80 to 120 ms, the signal from fat is suppressed because it is near the null point (inversion point) of magnetization recovery. Because fat in the body wall and mesentery is a major source of motion artifact, this sequence increases signal-to-noise and contrast-to-noise ratios.²³⁷⁻²⁴⁰ The sequence yields excellent lesion-to-liver contrast, which helps confirm the presence of a lesion or increase confidence in its absence. It also has a high sensitivity for fatty infiltration, periportal changes, and biliary dilation but suffers from a relatively low signal-to-noise ratio. A short inversion time makes the image both T1 and T2 dependent, so that structures with long T1 and T2 values, such as tumors, are conspicuously bright. The STIR sequence is usually not used by itself but is useful in confirming the presence of a lesion or increasing confidence in its absence.

Fat Suppression Techniques

Fat suppression allows the detection and suppression of signal from adipose tissue. This can be achieved in three ways: frequency-selective fat saturation, inversion recovery imaging, and opposed-phase imaging.²⁴¹

Frequency-selective fat saturation relies on the application of a saturation radiofrequency pulse with the same resonance frequency as that of lipids to each slice-selection radiofrequency pulse. A homogeneity spoiling gradient pulse is applied immediately after the saturation pulse to dephase the lipid signal. The signal excited by the subsequent slice-selection pulse contains no contribution from lipid.²⁴¹ Frequency-selective fat suppression can be used with both gradient-echo and spin-echo sequences. It helps suppress the fat signal on fast spin-echo T2-weighted images, on which fat is relatively bright because of the application of the multiple 180-degree pulses. Fatty liver may diminish conspicuity of focal high signal intensity lesions. Application of frequency-selective fat suppression to contrast-enhanced T1-weighted images helps minimize this effect. In the presence of magnetic field or radiofrequency inhomogeneities and imperfect radiofrequency profiles, the homogeneity of the frequency-selective fat saturation is appreciably compromised.

Fat saturation with inversion recovery imaging is based on differences in the T1 of tissues. The T1 of adipose tissue is shorter than the T1 of water. Therefore, the longitudinal magnetization of adipose tissue will recover faster than that of water after a 180-degree inversion pulse. If a 90-degree pulse is applied at the null point of adipose tissue, adipose tissue will produce no signal, whereas water will continue to produce a signal.²⁴¹

Opposed-phase imaging works best to detect small amounts of fat on T1-weighted gradient-echo images.²⁴²⁻²⁴⁴ Fat protons resonate at a slightly lower frequency than water protons, such that the two constantly fall in and out of phase with each other. When fat and water exist in the same voxel (as in fatty transformation), choosing an echo time when their signals are out of phase results in signal loss.²⁴⁵ Normal liver and most cancers do not contain an observable amount of triglycerides, so that the image intensity remains the same on in-phase and opposed-phase images. In the presence of fatty change, the signal intensity of the liver decreases on opposed-phase images compared with in-phase images. Likewise, fat within lesions can be detected, improving lesion characterization.²⁴⁶ Instead of merely suppressing the signal from fat, opposed-phase imaging can also be used to decompose fat and water proton signals by use of their resonant frequency difference and to isolate these two components into two separate images. Such water-fat separation methods are based on work by Dixon.²⁴⁷ Modifications of the Dixon technique, such as IDEAL, have been developed to overcome local magnetic field (B_0) or radiofrequency (B_1) inhomogeneities at higher field strengths.²⁴⁸

Magnetic Resonance Contrast Agents

MR contrast agents can improve liver lesion detection and characterization.^{249,250} They can be categorized on the basis of their distribution into extracellular fluid agents, hepatobiliary-specific agents, reticuloendothelial agents, and blood pool agents.²⁵¹

Extracellular Fluid Agents. This class of agents includes the gadolinium chelates gadopentetate dimeglumine (Gd-DTPA) and gadoteridol (Gd-HP-DO3A). These paramagnetic agents act by shortening T1 relaxation times.^{252,253} These agents function in a manner analogous to iodinated CT contrast agents by

rapidly diffusing from the intravascular space to the extracellular space. Thus, they require rapid imaging to exploit perfusion differences between liver lesions and normal hepatic parenchyma. Rapid breath-hold 3D fat-saturated spoiled gradient-echo T1-weighted techniques are most frequently used, allowing the entire liver to be imaged in a single breath hold (15–25 seconds). Although the signal-to-noise ratio is less than that of higher resolution sequences, such as spin-echo sequences, this technique allows faster imaging in multiple phases of contrast enhancement, analogous to multiphasic spiral CT. Images are obtained before the administration of contrast material, in the arterial predominant phase, in the portal predominant phase (Fig. 83-25), and then during equilibrium. The arterial dominant phase is usually 25 seconds after injection, and the portal venous phase is 70 seconds after injection. Some institutions use a test bolus or bolus tracking instead of relying on fixed time delays, especially in patients with poor cardiac status.

Dynamic contrast enhancement has proved useful in characterizing hemangiomas, detecting hypervascular metastases or small hepatocellular lesions, and detecting enhancement in the central scar of focal nodular hyperplasia.^{254–256} It has been shown not only to improve the distinction between benign and malignant lesions but also to achieve a specific diagnosis in many focal lesions.²⁵⁷ Gadolinium chelate-enhanced 3D rapid gradient-echo images have been found superior to T2-weighted fast spin-echo images (with or without fat suppression and breath holding) for the detection of focal liver masses.²⁵⁸

Hepatobiliary-Specific Agents. The gadolinium-based agents gadoxetic acid (Gd-EOB-DTPA) and gadobenate dimeglumine (Gd-BOPTA) and the no longer commercially available manganese-based mangafodipir trisodium (Mn-DPDP) are taken up to varying degrees by functioning hepatocytes and are excreted in the bile. Whereas hepatic uptake is approximately 50% for gadoxetic acid, it is only 5% for gadobenate dimeglumine. The resulting T1 shortening of the liver, biliary tree, and hepatocyte-containing lesions (Fig. 83-26) results in an increased contrast-to-noise and signal-to-noise ratio for non-hepatocellular lesions.²⁵⁹ Secretion in the biliary tract enables

diagnostic imaging of the bile ducts, such as evaluation for bile leaks. Because the hepatobiliary phase of enhancement is relatively prolonged, the imaging in this phase does not have to be precisely timed (as it does in dynamic imaging with extracellular fluid agents), and high spatial resolution sequences in separate breath holds can be used. Because gadoxetic acid and gadobenate dimeglumine are in part excreted through the kidneys, the vascularity of a lesion can also be assessed, like an extracellular agent.^{260,261} Liver MRI after administration of gadobenate dimeglumine can increase the detection of liver lesions in patients with primary malignant hepatic neoplasm, especially for lesions smaller than 1 cm.²⁶² A 56% increased detection of liver metastases has been demonstrated with the use of these contrast agents.^{259–261} Decreased hepatic blood flow and liver dysfunction diminish hepatic enhancement.²⁶³

Reticuloendothelial Agents. This class of agents includes superparamagnetic iron oxide particles coated with dextran, ferumoxide (AMI-25), and ultrasmall superparamagnetic iron oxide agents like SHU-555A and AMI-227.^{264–266} Uptake occurs in endothelial and Kupffer cells of the liver. On T2* weighted imaging, areas of normal liver containing Kupffer cells that have taken up superparamagnetic iron oxide particles appear dark, whereas lesions without hepatocytes will remain bright. The effect depends on the strength of the applied magnetic field.²⁶⁷ Reticuloendothelial system agents are used primarily for lesion detection but are no longer available in the U.S. market.

Blood Pool Agents. Gadofosveset trisodium is an intravascular gadolinium-based contrast agent available in both the United States and Europe. Its high degree of albumin binding slows the renal excretion and therefore greatly increases its relaxivity. The approved indication in the United States is vascular imaging, and there are few publications on the use of intravascular contrast agents for liver imaging. It has potential for high-resolution steady-state arterial, portal venous, and hepatic venous imaging in the liver as well as quantitative perfusion imaging.

Diffusion-Weighted Magnetic Resonance Imaging

The advent of echoplanar imaging techniques enabled diffusion-weighted MRI of the abdomen.^{268–270} Diffusion-weighted imaging can be performed relatively quickly (as short as two breath-hold acquisitions) and allows lesion detection without contrast agent injection, which makes it attractive in patients with decreased renal function. Low b values (below 100 s/mm²) provide black-blood images, with high inherent tissue contrast and robust image quality. In the liver, diffusion-weighted imaging provides higher sensitivity for lesion detection than T2-weighted images and has inferior to equivalent sensitivity compared with contrast-enhanced T1-weighted images.^{271,272}

Higher b values (≥ 500 s/mm²) are used for lesion characterization by comparing lesion signal intensity and lesion signal intensity changes with liver parenchyma as well as by quantitative assessment of the apparent diffusion coefficient (ADC). Malignant lesions (which are usually more cellular) typically demonstrate restricted diffusion, which is manifested as high residual signal intensity on images obtained with high b values compared with background liver parenchyma, as opposed to benign nonsolid lesions, such as liver cysts and hemangiomas, with ADC of malignant lesions visually equal to or lower than that of surrounding liver parenchyma.²⁷³ Quantitative ADC threshold values have been investigated for

Figure 83-25 Liver MRI: T1-weighted gradient-echo image after administration of gadolinium. The aorta, IVC, and hepatic parenchyma are brightly enhanced. Gadolinium enhancement affords improved characterization of focal lesions.

Figure 83-26 Liver MRI. Noncontrast image (A). Post-gadobenate, fat-suppressed, T1-weighted, gradient-echo images: arterial phase (B) and venous phase (C) images. Delayed images at 3 minutes (D) and 90 minutes (E) illustrate persistent and prolonged enhancement of liver. There is opacification of biliary tract (E) due to excretion of contrast material.

lesion characterization, with variable accuracy, depending on the patient population and lesion type.

A major limitation to the widespread use of diffusion-weighted imaging has been the fact that the proposed ADC cutoffs depend on the b values used for acquisition. A meta-analysis by Xia and colleagues²⁷⁴ documented significantly higher ADC values for benign lesions compared with malignant lesions, with variable overlap. Of note, the accuracy decreases when benign hepatocellular lesions such as focal nodular hyperplasia and hepatocellular adenomas are included.²⁷²

Elastography

MRI techniques have become available to noninvasively diagnose and grade hepatic fibrosis by analyzing the propagation of mechanical waves through tissue.²⁷⁵ Stiffness of the hepatic parenchyma as an indicator of fibrosis is derived from gradient-echo images acquired as externally generated shear waves propagate through the liver. Motion-sensitizing gradients similar to those used in phase contrast MR angiography are applied during the image acquisition. The resulting phase contrast images, which depict propagating mechanical waves, are processed to generate quantitative stiffness maps, also known as

elastograms. These maps depict tissue stiffness as the elastic shear modulus on a per-pixel basis (in units of kilopascals) and are often displayed with a color scale.²⁷⁶

Because elastography has been shown to differentiate between low- and high-grade fibrosis, it could be used for non-invasive longitudinal monitoring of hepatic fibrosis.²⁷⁷ However, MR elastographic assessment of liver fibrosis conceivably may be confounded by a variety of factors expected to alter liver stiffness, including hepatic inflammation, steatosis, hepatic vascular congestion, cholestasis, and portal hypertension, and the technique has yet to be validated in large clinical trials.

Spectroscopy

Spectroscopy is being investigated to quantify the degree of steatohepatitis and to reveal a necroinflammatory response in the setting of chronic liver disease.²⁷⁸ Although it is largely restricted to research protocols, this technique has been applied in a general population to establish the prevalence of hepatic steatosis. The good correlation of values obtained with spectroscopy with the results of liver biopsy makes spectroscopy a promising method for estimating the hepatic triglyceride content.²⁷⁹ However, MR spectroscopy is not widely used for

these purposes and has not been validated for routine clinical applications.

Magnetic Resonance Perfusion Imaging

Perfusion MRI represents a useful alternative to CT perfusion imaging for surveillance of hepatocellular carcinoma. Jackson and coworkers²⁶⁰ reported 3D dynamic contrast-enhanced perfusion MRI in humans for lesion-specific permeability mapping. Perfusion characteristics of lesions with dual blood supply were unreliable because they used only the hepatic arterial supply as input function.²⁸⁰ Annet and colleagues^{261,268} reported increased fractional arterial perfusion and decreased mean transit time when they evaluated humans with cirrhosis by dual-input, single-compartment perfusion MRI with a standard low-molecular-weight contrast material. Further technical improvements are required.

Artifact Minimization

Several techniques to minimize artifact have been used, including obtaining multiple signal averages, respiratory compensation, fat suppression, and saturation pulses for abdominal wall fat. Strategies depend on the magnet at hand because 3T systems require an approach different from that for 1.5T systems.²⁸¹

Selecting an Appropriate Imaging Technique

Technologic advances in radiology offer several imaging tools for evaluation of focal liver lesions. These include ultrasound, CT, and MRI. Choosing the most appropriate imaging modality

for evaluating the liver lesion under question depends on the information required from imaging for clinical management decisions. Although ultrasound might be an appropriate examination for a patient with no prior medical history and increased alkaline phosphatase and bilirubin levels, ultrasound is not an adequate screening test for hepatocellular carcinoma in a patient with cirrhosis and increased α -fetoprotein. Although MDCT serves as the first-line imaging modality for evaluation of the liver, MRI offers an attractive alternative to radiation-based CT examination. The clinical applications of MRI for evaluation of the liver are rapidly expanding because of availability of faster sequences and newer contrast agents. Indeed, in some centers, MRI is being used as the imaging modality of choice for evaluation of liver disease.²⁸²⁻²⁸⁴ However, in most centers, MRI is still reserved for certain clinical situations, such as further characterization of liver lesions detected on CT, patients with allergy to iodinated contrast agents, and work-up for hepatic resection.²¹¹ Intraoperative ultrasound has become a standard liver imaging tool for resection of liver metastases from colorectal carcinoma.²⁸⁵ The choice of appropriate imaging modality should be made on an individual case basis, depending on the lesion under question, availability of imaging facilities, and cost issues.

Acknowledgment

We would like to thank Drs. Saravanan Namasivayam, Mannudeep K. Kalra, and William C. Small, the authors of this chapter in the third edition, whose manuscript this chapter is built on, and Dr. Diego Martin, Department of Radiology, Emory University Hospital, Atlanta, for contributing some of the MR images for this chapter.

PERCUTANEOUS LIVER BIOPSY

Random

Brief Rationale. The first percutaneous liver aspiration was performed by German physician Paul Ehrlich in 1883, but the technique became widely accepted only after the landmark publication by Menghini in 1958.¹ It is likely that the intensive efforts to characterize and to quantify diffuse liver disease through magnetic resonance (MR) elastography, MR spectroscopy, and ultrasound elastography will at some point obviate the need for liver biopsy in many patients. However, liver biopsy currently remains the “gold standard” for parenchymal evaluation in the setting of diffuse hepatic disease.²⁻⁴ Current indications for nonfocal liver biopsy include the diagnosis and staging of cirrhosis, cholestatic liver disease, metabolic storage disease, and other infiltrative diseases.⁵

Preprocedural Evaluation and Contraindications. Patients should have nothing by mouth for 4 to 6 hours before a liver biopsy if intravenous sedatives are to be administered. Although there is wide variation in individual practices, the Society of Interventional Radiology has provided a consensus set of guidelines for periprocedural management of laboratory coagulation

parameters and medications that recommends checking preprocedural international normalized ratio (INR) in all patients and activated partial thromboplastin time (aPTT) in patients receiving unfractionated heparin with subsequent correction to INR below 1.5 and aPTT of less than 1.5 times the control value. Although these guidelines do not recommend checking platelets before the procedure, they do recommend correcting platelets to more than 50,000 in patients with known thrombocytopenia. Warfarin as well as antiplatelet agents such as clopidogrel should be discontinued for at least 5 days before biopsy.⁶ Although there is no consensus, many practices restart antiplatelet therapy such as clopidogrel 48 to 72 hours and warfarin 24 hours after the biopsy.⁵ There also is no consensus addressing the alteration of heparin therapy, although others have suggested holding heparin for between 2 and 6 hours before the procedure and restarting heparin 12 hours after the procedure.⁷

Although no absolute contraindications to liver biopsy exist, relative contraindications, such as the patient's cooperation, extrahepatic biliary obstruction, and severe coagulopathy, may warrant consideration of transjugular liver biopsy in specific cases. However, correction of coagulation abnormalities can also be performed to proceed safely with percutaneous liver biopsy.

Guidance and Technique. Percutaneous liver biopsy is a safe procedure that can be performed on an outpatient basis. Imaging guidance is becoming increasingly prevalent and has multiple advantages over palpation- or percussion-guided techniques, including a decreased complication rate and superior diagnostic yield.⁸ Ultrasound is the preferred imaging modality in most cases because of low cost, real-time guidance, multiplanar imaging, portability, visualization and avoidance of major blood vessels and lung, and lack of ionizing radiation. Imaging guidance with ultrasound has also been shown to decrease the number of major and minor complications.^{9,10} Although ultrasound-guided liver biopsies are slightly more costly on a per-procedure basis than biopsies guided by palpation, cost-effectiveness analyses have suggested that the other benefits of ultrasound guidance may reduce the overall cost of liver biopsy.^{11,12}

Ultrasound-guided biopsies can be performed through a subcostal or intercostal approach. A subcostal approach is generally favored over an intercostal puncture because of a lower risk of pneumothorax or intercostal artery injury.¹³ Sonographically guided interventions can be performed either by a free-hand technique (which provides for greater freedom in needle placement) or with an attached biopsy guide (which provides greater accuracy). Local anesthetic should be liberally applied from the skin entry site down through the subcutaneous fat and peritoneum directly onto the liver capsule. If possible, the biopsy needle should be placed during a breath hold to reduce

Figure 84-1 Random liver biopsy. Ultrasound image demonstrates real-time percutaneous needle placement for a random liver biopsy in the evaluation of a patient with known hepatitis C through a subcostal approach.

the risk of capsule laceration and to facilitate biopsy at the site of local anesthetic administration.¹⁴ Although the American Association for the Study of Liver Diseases (AASLD) recommends a 16-gauge biopsy needle of 2 or 3 cm in length for the diagnosis, grading, and staging of diffuse parenchymal liver diseases, the use of 18-gauge cutting needles is common in many institutions.⁵ The patients should be monitored for 2 to 4 hours after the procedure in a recovery unit before discharge (Fig. 84-1).

Complications. The most common complication after liver biopsy is pain, the exact cause of which is unknown but may be due to a small bile leak or subcapsular hematoma. Most post-biopsy pain is readily managed with intravenous or oral analgesics.¹⁵ Bleeding is the most important complication after liver biopsy. Subclinical bleeding not requiring specific intervention occurs in up to 23% of liver biopsies, and severe hemorrhage requiring transfusion or other intervention occurs in 0.35% to 0.5%.^{8,16-18} Other potential complications include damage to adjacent organs, pneumothorax, hemothorax, peritonitis, and death. The reported mortality rate after liver biopsy is approximately 0.01%.⁵

Image-Guided Percutaneous Liver Mass Biopsy

Indications

Hepatocellular Carcinoma. The recommendations for hepatocellular cancer screening have recently been updated by the AASLD, and surveillance for patients at high risk for the development of hepatocellular carcinoma (HCC) is recommended with ultrasound every 6 months.¹⁹ Routine serum α -fetoprotein is no longer recommended for screening or diagnosis because of lack of sensitivity and specificity.^{20,21} If a nodule larger than 1 cm is identified on screening ultrasound, contrast-enhanced multiphasic computed tomography (CT) or magnetic resonance imaging (MRI) is performed. Liver biopsy is rarely indicated in the evaluation for HCC, particularly in the setting of cirrhosis, because of the ability to diagnose most cases of HCC with imaging alone. In addition, the small but real risk of bleeding and tumor seeding generally outweighs the benefit of histologic diagnosis, given the extremely high pretest probability of HCC with imaging. The risk of tumor seeding along a biopsy

track is estimated at 0.9% per patient per year.²² At most institutions, HCC is predominantly an imaging diagnosis, and patients are managed without histologic confirmation.^{23,24} There are currently two sets of imaging criteria for the diagnosis of HCC on CT or MRI, the Liver Imaging Reporting and Data System (LI-RADS) and the United Network for Organ Sharing (UNOS)/Organ Procurement and Transplant Network (OPTN) criteria.^{25,26} Both sets of criteria incorporate the presence or absence of arterial enhancement, washout, capsule, and growth to diagnose HCC. Percutaneous image-guided liver biopsy is reserved for lesions that do not meet strict imaging characteristics by MRI and CT.¹⁶ However, even biopsy is not 100% accurate for the diagnosis of small HCCs.²⁷

Other Focal Liver Lesions. Targeted liver biopsies are frequently performed in the evaluation of focal hepatic abnormalities not suspected of being HCC. CT and MRI are often used for first-line characterization of focal hepatic abnormalities because of the ability to definitively diagnose many HCCs, hemangiomas, adenomas, and focal hepatic steatosis. Other lesions have a less characteristic imaging appearance and typically require biopsy for tissue diagnosis.²⁸ As metastatic lesions are more common than primary hepatic malignant disease, the majority of targeted hepatic biopsies are performed in an effort to evaluate focal liver lesions in the setting of a known primary malignant neoplasm. Sampling the metastatic lesions in the liver (or elsewhere) can serve both to make a diagnosis and to stage the disease concurrently. Thus, liver biopsy is often performed, even when the site of extrahepatic primary malignant disease is suspected or known (Fig. 84-2).

Preprocedural Evaluation. The preprocedural evaluation for patients undergoing percutaneous liver biopsy for a focal mass lesion in the liver is similar to that described for image-guided random liver biopsy.

Guidance and Technique. Most image-guided liver biopsies are performed under either ultrasound or CT guidance. Ultrasound is the preferred imaging modality worldwide for liver biopsy guidance for the reasons described in the preceding section. However, CT guidance has been proved to be effective and safe for experienced operators.²⁹ The advantages of ultrasound include less expense, lack of radiation, and real-time imaging as well as ability to access lesions at the hepatic dome. The disadvantages of ultrasound include user dependence and difficulty of imaging large patients. The lack of inherent tissue contrast often makes identification of targets difficult by non-contrast CT. Both core needle and fine-needle aspiration techniques can be used for liver biopsy, but most studies favor obtaining a core needle specimen because of increased specificity and accuracy in diagnosis and subtyping of tumors, superiority in diagnosis of benign lesions, decreased biologic sampling errors, and preservation of tissue architecture.³⁰⁻³² In biopsy of a focal liver lesion, every attempt should be made to perform the biopsy through a cuff of normal liver parenchyma to decrease the risk of bleeding.³³ With larger masses, core samples should be taken from the periphery of the lesion to avoid central necrosis.³⁴

Results and Complications. Image-guided biopsy of focal liver lesions has been shown to have a high diagnostic accuracy (94.5%-100%), even for lesions between 0.5 and 1.0 cm.^{29,34-36} In patients with a known primary malignant neoplasm with a

Figure 84-2 Targeted liver biopsy. **A.** CT demonstrates a hypoattenuating left hepatic lobe lesion (arrow) in a patient with colorectal cancer. **B.** Subsequent ultrasound identified a corresponding targetoid liver lesion, and a targeted ultrasound-guided biopsy through the subcostal approach (**C**) revealed metastatic disease.

Figure 84-3 HCC biopsy track seeding.

A. Multiphase abdominal CT (arterial phase shown) in a patient with cirrhosis demonstrated a vague mass in the left hepatic lobe that did not meet imaging criteria for HCC. **B.** Ultrasound-guided biopsy was performed through a subcostal approach, demonstrating well-differentiated HCC. The patient underwent successful liver transplantation. **C.** At 2-year follow-up, CT demonstrated a new soft tissue nodule in the anterior abdominal wall (arrow). This was surgically resected and proven to be well-differentiated HCC seeding along the previous biopsy track.

focal liver lesion, a second malignant neoplasm was diagnosed in 5% of cases, and a benign entity was identified in another 3.4%.³⁶ The complications associated with liver biopsy of a focal liver lesion are similar to those for random liver biopsy. The risk of tumor seeding after biopsy of HCC is high (0.76%-2.7%)

and is a catastrophic complication, potentially causing removal from the transplant list^{22,37,38} (Fig. 84-3).

Because most HCCs can be diagnosed on the basis of imaging findings without the need for tissue, biopsy of masses in cirrhotic patients should be rare and reserved for atypical cases

that do not meet LI-RADS or AASLD criteria. Tumor seeding after biopsy of metastatic liver lesions is rare and is usually associated with a generalized rapid growth in all tumor sites.^{39,40}

TRANSJUGULAR LIVER BIOPSY

Brief Rationale and Indication

Transjugular liver biopsy was first described in humans in 1970 and is the preferred technique for obtaining random tissue samples of the liver in patients with uncorrectable coagulopathies.⁴¹ The most common indications for performing transjugular liver biopsy are coagulopathy, massive ascites, and in conjunction with other procedures such as measurement of hepatic venous pressure gradient or hepatic/caval venography.⁴² Acute liver failure, early postoperative liver transplants, and congenital clotting disorders are also scenarios in which transjugular liver biopsy has been shown to be of benefit.⁴³⁻⁴⁵

Guidance and Technique

The right internal jugular vein is accessed under ultrasound guidance, and the right hepatic vein is cannulated through the inferior vena cava with an angled catheter. Continuous electrocardiographic monitoring throughout the procedure is recommended to detect arrhythmias induced by passage of the catheter through the heart. The right hepatic vein is preferred because of its angle with the inferior vena cava and the larger size of the right hepatic lobe. Hepatic venography is performed to confirm appropriate positioning. Peripheral punctures should be avoided because of the risk of capsular puncture.⁴⁶ The number of biopsy passes is operator dependent; however, an increased number of passes (four vs. three) has been shown to produce longer specimens and a greater number of complete portal tracts for histologic interpretation.⁴⁷

Results and Complications

Transjugular liver biopsy has been shown to have a high success rate with a tissue adequacy rate of approximately 96%. Technical failures are most commonly due to failure to cannulate the hepatic veins. Minor and major complication rates have been reported as 6.5% and 0.56%, respectively. The most common major complication is intraperitoneal hemorrhage secondary to perforation of the liver capsule. Mortality after transjugular liver biopsy is reported as approximately 0.1% and in most cases is due to intraperitoneal hemorrhage or ventricular arrhythmia.⁴⁸

Liver Aspiration and Drainage

HEPATIC ABSCESS

Epidemiology and Symptoms

The mortality from pyogenic liver abscess has decreased from approximately 40% to 6% in the modern era as a result of advances in cross-sectional imaging, antibiotic therapy, and percutaneous image-guided therapy.⁴⁹⁻⁵¹ The incidence of pyogenic liver abscesses has increased in Western countries and is now at a rate of 1.1 to 3.6 per 100,000 people. In Eastern countries such as Taiwan, a higher rate of liver abscesses (17.6 per 100,000) is due to increased rates of cholangitis and parasitic infections.⁵² Clinically, patients often present with vague signs and symptoms such as fever, chills, nausea, abdominal pain, and

leukocytosis. Most liver abscesses are diagnosed and monitored with CT, MRI, or ultrasound.

Most pyogenic liver abscesses in Western countries are due to biliary disease. Although pyogenic abscesses historically were most commonly due to *Escherichia coli*, more recent data suggest that *Klebsiella pneumoniae* is now the most common pathogen causing pyogenic liver abscesses in Western countries.⁵³ Other causative organisms in the West commonly include *Streptococcus* and *Staphylococcus* species, although polymicrobial infections are common. Culture and antimicrobial sensitivity results should always assist in guiding antimicrobial coverage.^{51,54,55} Other potential causes include septic pylephlebitis related to appendicitis, diverticulitis, and other inflammatory conditions of the intestine that are transmitted to the liver through the portal vein as well as postsurgical or post-traumatic injury, direct extension from contiguous organs, and after interventional oncologic treatments in patients with incompetent sphincters of Oddi.⁴⁹⁻⁵¹ Primary or metastatic liver malignant neoplasms can also rarely be manifested as liver abscesses.⁵²

Guidance and Technique

Minimally invasive image-guided percutaneous treatments such as needle aspiration and catheter drainage have supplanted surgical therapy for the treatment of liver abscesses, with significant decreases in hospital stay, overall cost, and morbidity.^{56,57} Surgery still plays an important role for the treatment of recalcitrant abscesses and in the setting of malignant disease. Abscesses smaller than 3 cm are usually treated successfully with parenteral antibiotics alone; however, aspiration may be requested for microbial identification.⁵⁸ Image-guided needle aspiration has been shown to be highly effective for unilocular abscesses smaller than 5 cm.^{56,59,60} Multiple aspiration sessions may be required for complete success. Image-guided percutaneous catheter drainage is preferred for abscesses larger than 5 cm, multiloculated abscesses, or those in direct continuity with bile ducts or bowel.^{56,57,60,61}

Preprocedural assessment should include evaluation of coagulation parameters with a target INR below 1.5, aPTT of less than 1.5 times the control value, and platelet count above 50,000/ μ L.⁶ Ultrasound or CT guidance can be used for aspiration or catheter drainage on the basis of the operator's preference. In choosing a puncture path, the least amount of hepatic parenchyma should be traversed, and care should be taken to avoid damaging adjacent organs or traversing the pleura because of the risk of empyema. Needle aspiration is usually performed with an 18-gauge needle; catheter drainage may be performed by the Seldinger or trocar technique with placement of a multi-side hole, locking catheter. Drainage is usually continued until the patient demonstrates clinical improvement and drainage output is less than 10 to 20 mL/day.⁶² A fluoroscopic sinogram can be obtained before catheter removal to assess the residual size of the cavity and the presence of fistulization to the bowel or biliary system (Fig. 84-4).

Results and Complications

Success rates for image-guided needle aspiration of simple pyogenic liver abscesses smaller than 5 cm approach 100% with minimal complications.^{56,59,60} Catheter drainage success rates have varied significantly in the literature from 66% to 100%, probably secondary to abscess and patient factors. Higher failure rates have been associated with the presence of advanced malignant disease, particularly necrotic infected tumors, and

Figure 84-4 Hepatic abscess drainage. **A** and **B**. Initial axial T2 and coronal T2 single-shot fast spin-echo MR cholangiopancreatography images from a patient who presented with a hepatic abscess demonstrate a large heterogeneous T2 intense lesion in segment III of the liver (arrowhead) with adjacent intrahepatic biliary dilation (arrow). The patient was treated with a multi-side hole pigtail drain in the abscess, an internal/external biliary drain through the peripheral dilated biliary radicles of segment III, and intravenous antibiotics for a polymicrobial infection. **C**. Fluoroscopic image after drain placement with injection of contrast material into the abscess cavity demonstrates communication to the biliary system (arrow). The abscess developed secondary to a benign intrahepatic stricture that was treated with repeated balloon dilation (images not shown). **D**. Follow-up pullback cholangiogram demonstrates no residual stricture and resolution of the intrahepatic abscess. **E** and **F**. Follow-up axial T2 and coronal T2 single-shot fast spin-echo MR cholangiopancreatography images 3 months later demonstrate complete resolution of the intrahepatic abscess and biliary dilation in segment III.

the presence of fistulization to an obstructed biliary system.^{57,61} The risk of complications is minimal; complications such as pneumothorax, intraperitoneal hemorrhage, and mild pain are the most frequently reported.

Hepatic Venous Pressure Gradient

BRIEF RATIONALE AND INDICATIONS

Portal hypertension is a complication of chronic liver diseases and is responsible for many of the most severe clinical consequences of cirrhosis. Whereas noninvasive measurements of portal pressure such as elastography are currently being developed, direct measurement of the hepatic venous pressure gradient is the current gold standard for estimating the degree of portal hypertension.⁶³⁻⁶⁵

First described in 1951, hepatic venous pressure gradients can aid in the diagnosis and classification of portal hypertension; assessment of prognosis in patients with cirrhosis and portal hypertension-related clinical events including ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, and variceal bleeding; monitoring of response to pharmacologic therapy; and preoperative evaluation in patients with cirrhosis

selected for hepatic resection.^{66,67} The hepatic venous pressure gradient is obtained by introducing a balloon occlusion catheter into a hepatic vein and measuring the difference between the occluded venous pressure and free venous pressure. The occlusion of a hepatic vein blocks blood flow in the distal hepatic veins and in the sinusoids; thus catheter pressure measured in this position reflects the pressure in the sinusoids, which in turn reflects portal pressure in sinusoidal or post-sinusoidal portal hypertension. Pressure changes within the central venous system are corrected for by subtracting the free hepatic venous pressure from the wedged hepatic venous pressure. This results in a hepatic venous pressure gradient, with clinically significant portal hypertension defined as more than 12 mm Hg.⁶⁷

$$\begin{aligned} \text{Hepatic vein pressure gradient (HVPG)} \\ &= \text{Wedged hepatic venous pressure (WHVP)} \\ &\quad - \text{Free hepatic venous pressure (FHVP)} \end{aligned}$$

GUIDANCE AND TECHNIQUE

By use of a transjugular approach and fluoroscopic guidance, a mean pressure measurement is first recorded in the

retrohepatic inferior vena cava. All pressure measurements should be recorded with the transducer in a fixed position in the midaxillary line at the level of the right atrium. An occlusion balloon catheter is then advanced into either the right or middle hepatic vein, and the free hepatic venous pressure is measured in the hepatic vein 2 to 4 cm from its opening into the inferior vena cava. The balloon catheter should then be positioned in the middle third or at the transition zone between the middle and distal thirds of the hepatic vein and inflated until complete occlusion is observed by deformation of the balloon. The pressure recording should be allowed to stabilize for 45 to 60 seconds, and then a mean pressure is recorded for the wedged hepatic venous pressure. This process should be repeated at least three times, and finally a wedged hepatic venogram is obtained to evaluate for any venous-to-venous shunting to another hepatic vein that would result in underestimation of the wedged hepatic venous pressure. If venous shunting is identified, the balloon catheter should be placed distal to the shunting; if this is not technically feasible, another hepatic vein should be selected for interrogation.^{68,69}

RESULTS AND COMPLICATIONS

The use of balloon occlusion catheters has been shown to correlate more accurately with directly measured portal pressures during placement of transjugular intrahepatic portosystemic shunts (TIPS) compared with the use of an end-hole catheter wedged into a hepatic venule.⁷⁰ Technical success rates have been reported above 95%, and failure is usually the result of hepatic venous occlusion. Severe postprocedure complications are exceedingly uncommon.⁶⁷

Transjugular Intrahepatic Portosystemic Shunt

BRIEF RATIONALE AND INDICATIONS

TIPS is a percutaneous image-guided procedure that has proved to be beneficial for the treatment of complications of portal hypertension. First described in an animal model by Rösch and coworkers⁷¹ in 1969, a TIPS is a constructed channel within the liver connecting a portal vein branch to a hepatic vein with the goal of creating a portosystemic shunt to decrease portal venous pressure. A TIPS is created under fluoroscopic guidance by placing a stent graft from a hepatic vein (most commonly the right hepatic vein) through the liver parenchyma into an intrahepatic portal venous branch (most commonly the right portal vein). Another variation is a direct intrahepatic portosystemic shunt, which was first described in 2001.⁷² A direct intrahepatic portosystemic shunt is created with use of intravascular ultrasound, passing a needle from the inferior vena cava through the caudate lobe into the portal vein. Subsequent stent placement is performed under fluoroscopic guidance in a fashion similar to TIPS placement. The strongest evidence of TIPS efficacy has been established for secondary prevention of variceal bleeding and treatment of refractory ascites.⁷³ Other indications for TIPS creation include refractory acute variceal bleeding, portal hypertensive gastropathy, hepatorenal syndrome (types 1 and 2), Budd-Chiari syndrome, hepatic hydrothorax, hepatic veno-occlusive disease, and hepatopulmonary syndrome.⁷⁴⁻⁸⁰

RELATIVE AND ABSOLUTE CONTRAINDICATIONS

Absolute contraindications to TIPS placement include congestive heart failure, severe tricuspid regurgitation, severe pulmonary hypertension (mean pulmonary pressure >45 mm Hg), uncontrolled systemic infection or sepsis, and unrelieved biliary obstruction. Relative contraindications include anatomic issues that can reduce the technical success of shunt placement, such as polycystic liver disease, extensive primary or metastatic malignant disease (especially centrally near the porta hepatis), and obstruction of the hepatic veins or thrombosis of the portal venous system. Hepatic artery thrombosis, severe coagulopathy or thrombocytopenia, and the presence of hepatic encephalopathy may also significantly increase the risk of postprocedure complications.⁷³

Preprocedure evaluation includes complete laboratory work-up consisting of a complete blood count, coagulation panel, and comprehensive metabolic panel. Significant thrombocytopenia (platelet count <50,000 cells/ μ L), anemia (hematocrit <25%), or coagulopathy (INR > 1.5) should be corrected and arrangements made for crossmatched blood products. Recent cross-sectional imaging within 1 month should be reviewed to assess for vascular patency and anatomic considerations. If recent imaging is unavailable or an abrupt deterioration of hepatic function occurs, an urgent or emergent ultrasound with Doppler evaluation of the hepatic vasculature may be warranted to assess vascular patency. Echocardiography is also recommended to assess cardiac function and to specifically assess for pulmonary arterial hypertension.⁷³

GUIDANCE AND TECHNIQUE

TIPS procedures are mostly performed by use of general anesthesia with endotracheal intubation. The right hepatic vein is accessed through the right internal jugular vein, and balloon occlusion hepatic venography using carbon dioxide can be performed to visualize the course and flow in the portal venous system. Fluoroscopically guided needle passes are then made to achieve portal venous access. Direct portal venous pressure is measured, and a portosystemic pressure gradient is calculated as the pressure difference between the main portal vein and right atrium. A stent graft is deployed so that the uncovered caudal portion of the stent remains in the portal vein, with the cranial end terminating near the junction of the hepatic vein and inferior vena cava. Polytetrafluoroethylene (PTFE)-covered stent grafts have become the standard of care for de novo TIPS placement compared with bare metal stents because of a lower rate of TIPS dysfunction, higher rate of primary patency, lower rate of clinical relapse, and decreased incidence of hepatic encephalopathy.⁸¹ After deployment, trans-TIPS portal venography and pressure measurements in the main portal vein and right atrium are repeated. In patients with variceal bleeding, a post-TIPS portosystemic gradient below 12 mm Hg should be achieved to prevent rebleeding.⁸² Retrospective studies have shown that variceal embolization with coils, cyanoacrylate, or sclerosing agents such as sodium tetradecyl sulfate in addition to TIPS placement significantly decreases the risk for recurrent variceal bleeding.^{83,84} For patients with refractory ascites, the Society of Interventional Radiology and the AASLD guidelines recommend reducing the portosystemic gradient to below 8 mm Hg.⁸⁵ A portosystemic gradient below 5 mm Hg has been

associated with an increase in the risk of liver failure and severe hepatic encephalopathy requiring an intervention such as TIPS reduction⁸⁶ (Fig. 84-5).

RESULTS

Success after TIPS placement can be classified as technical, hemodynamic, and clinical. Technically successful creation of a shunt from the hepatic vein to the portal vein and hemodynamic success in reduction of a portosystemic gradient to below 12 mm Hg with nonfilling of gastroesophageal varices should be achieved in more than 95% of cases.⁸⁷ Clinical success for the separate indications for TIPS placement varies among studies because of different inclusion and evaluation criteria. Meta-analyses evaluating TIPS for secondary prevention of variceal bleeding compared with various forms of endoscopic therapy found a threefold decrease in the risk of recurrent bleeding after TIPS with similar all-cause mortality rates. However, a more than twofold increased risk for development of hepatic encephalopathy was noted after TIPS.^{88,89} A multicenter randomized controlled trial in high-risk patients with acute variceal bleeding demonstrated a statistically significant decrease in treatment failure and mortality for patients undergoing TIPS placement compared with those treated with repeated endoscopy and pharmacotherapy.⁷⁴

In the treatment of refractory ascites, a meta-analysis of randomized controlled trials demonstrated a 7.1-fold reduction in the risk of recurrent ascites, with rates of improvement ranging from 38% to 84% after TIPS compared with 0% to 43% after large-volume paracentesis.⁹⁰ No significant survival advantage for TIPS was found in early studies. A more recent randomized controlled trial in a select group of patients with preserved hepatic and renal function did demonstrate a significant survival advantage after TIPS placement.⁹¹ The rate of hepatic encephalopathy in this group of patients was 2.2-fold higher after TIPS.⁹⁰ TIPS also is likely to lead to survival prolongation

in patients with Budd-Chiari syndrome, with 1- and 5-year liver transplant-free survival of 88% and 78%, respectively, with a median Model for End-Stage Liver Disease (MELD) score of 17.⁷⁵ At least partial improvement in clinical symptoms is experienced in 68% to 82% of patients with hepatic hydrothorax, and complete resolution of the hydrothorax occurs in 57% to 71% after TIPS creation.⁷⁸

COMPLICATIONS

Patients with a MELD score above 18 have a significantly higher mortality 3 months after TIPS than that of patients with a MELD score of 18 or less.⁷² Technical complications such as transcapsular puncture may occur in up to 33% of cases but result in significant intraperitoneal hemorrhage in only 1% to 2%.⁸⁵ Stent migration or misplacement into the inferior vena cava or portal vein may occur in up to 10% to 20% of cases. Creation of the shunt results in diversion of portal blood flow past the metabolic filtering effect of the hepatic parenchyma, which can lead to new or worsening hepatic encephalopathy in 10% to 44% of patients. Patients of advanced age, with a past history of encephalopathy, and with advanced liver disease are at increased risk for development of hepatic encephalopathy. However, encephalopathy usually responds to medical treatment, and only rarely is TIPS reduction or occlusion necessary.⁸⁵ Other potential complications, such as hepatic infarction, creation of a biliary-venous or hepatic artery–portal vein fistula, hemolysis, sepsis, and TIPS infection, are much rarer.

The introduction and widespread use of PTFE-covered stent grafts for TIPS creation has led to a dramatic improvement in long-term TIPS patency. The incidence of shunt dysfunction with bare metal stents ranges from 18% to 78%, probably secondary to intimal hyperplasia protruding through the stent interstices.⁸⁵ Primary patency rates at 1 year with PTFE-covered stent grafts have been reported at 81% to 86%^{81,92} (Fig. 84-6).

Figure 84-5 TIPS placement. **A.** Dual iodinated contrast material injection through the sheath in the right hepatic vein and the pigtail catheter in the main extrahepatic portal vein. **B.** Post-stent deployment injection in the main portal vein. Note the metallic ring on the distal portion of the stent (white arrow). The stent proximal to the ring is covered and intraparenchymal. The stent distal to the ring is uncovered and intravascular in the right portal vein. Also note the proximal aspect of the stent at the confluence of the right hepatic vein and inferior vena cava (arrowhead). Post-stent venogram also demonstrates nonfilling of the coronary vein (black arrow).

Figure 84-6 Hepatic venous stenosis after TIPS placement. Fluoroscopic images from TIPS revision in a patient with recurrent ascites after original TIPS placement. Doppler ultrasound before the procedure demonstrated temporal increase in the velocity in the hepatic venous end of the shunt (images not shown). **A.** A portal venogram demonstrates hepatic venous stenosis with the proximal portion of the stent in the hepatic parenchyma short of the confluence of the right hepatic vein and inferior vena cava (arrow). **B.** A second PTFE-covered stent was placed and extended to the inferior vena cava (arrow). Portal systemic gradient decreased from 13 to 7 mm Hg after stent deployment, and the patient's ascites resolved.

FOLLOW-UP AND TIPS REVISION

Despite the decrease in TIPS dysfunction after implementation of PTFE-covered stent grafts, regular shunt surveillance is recommended. One protocol for surveillance uses Doppler ultrasound at 1, 3, 6, and 12 months after TIPS creation and every 6 to 12 months thereafter, depending on the patient's clinical status.⁹³ A significant degree of variability regarding the sensitivity and specificity of Doppler ultrasound for detection of TIPS dysfunction has been reported. Measured velocities throughout the course of the shunt should range between 90 and 190 cm/s.⁹⁴ Direction of flow within the left portal vein should be hepatofugal (toward the shunt) after TIPS placement. Left portal vein hepatopetal flow (toward the liver) is therefore indicative of shunt dysfunction.⁹⁵ Temporal changes in the peak velocity greater than 50 cm/s have also been recommended as an indication for venography and pressure measurements, which are the gold standard for assessing TIPS dysfunction.⁹⁶ Patients with symptoms suggestive of recurrent portal hypertension in the setting of normal findings on Doppler ultrasound also warrant further investigation with venography. In the setting of TIPS dysfunction secondary to stenosis, repeated stenting has been shown to lead to better patency than angioplasty alone. Patients with a bare metal stent requiring reintervention should be revised with a PTFE-covered stent graft.^{85,97}

Interventional Oncology in the Liver

Liver-directed locoregional therapies for unresectable primary and metastatic malignant neoplasms continue to evolve with advances in ablative and endovascular technologies and techniques. The goal of liver-directed therapy in patients with hepatic malignant neoplasms can be multifaceted and vary from allowing a patient with unresectable disease to become

a resection or transplant candidate to curative treatment in nonsurgical candidates or improvement of survival and quality of life in a palliative setting. The choice of treatment modality depends on multiple factors including the presence of underlying liver dysfunction, tumor type, overall tumor burden, number and location of tumors, and patient factors such as performance status and functional liver reserve. The most common locoregional therapies currently being used are portal vein embolization (PVE), radiofrequency (RF) and microwave (MW) ablation, transarterial chemoembolization with or without drug-eluting beads (TACE and DEB-TACE), and transarterial radioembolization. Other liver-directed therapies, such as percutaneous ethanol ablation, cryoablation, and other ablative technologies such as laser-induced interstitial thermotherapy, high-intensity focused ultrasound, irreversible electroporation, hepatic arterial infusion chemotherapy, and transarterial bland embolization, have also been reported and play a lesser role in current treatment algorithms. The latter techniques either are still in development or are of historical interest and are beyond the scope of this chapter.

PREOPERATIVE PORTAL VEIN EMBOLIZATION

Brief Rationale

Surgical resection of both primary malignant neoplasms and liver metastases remains the mainstay of curative therapy. Continued advances in surgical techniques have led to improved overall patient outcomes; however, major hepatic resection places patients at risk for liver insufficiency. Determination of the volume of liver that remains after surgery, the future liver remnant (FLR), has been shown to be a strong independent predictor of postoperative complications.⁹⁸ In patients with an inadequate FLR, PVE of the lobe to be removed can cause hypertrophy to the FLR and atrophy of the embolized

segment. PVE has been most commonly used in patients with colorectal metastatic disease, intrahepatic cholangiocarcinoma, and HCC.⁹⁹ Whereas the exact mechanisms of hepatocyte regeneration are unknown, studies have demonstrated that in addition to redistribution of portal venous blood flow, PVE also induces an increase in hepatic growth factor and transforming growth factors α and β .¹⁰⁰ FLR hypertrophy rates have been noted to be impaired in patients with underlying cirrhosis or fibrosis and in diabetic patients.⁹⁹

Indications

Patients undergoing major hepatic resection may benefit from preoperative determination of the FLR. CT volumetry is used to measure the volume of the FLR. Calculations with either the measured total liver volume minus the tumor burden volume or the estimated total liver volume by use of body surface area are performed to assess percentage of FLR after resection. PVE is recommended in patients with preserved liver function and an FLR of less than 20%, patients with either hepatic steatosis or significant exposure to hepatotoxic chemotherapy and an FLR of less than 30%, and patients with well-compensated cirrhosis and an FLR of less than 40%.¹⁰¹⁻¹⁰³ Relative contraindications to PVE include extrahepatic metastases, uncorrectable coagulopathy, extensive tumor burden precluding safe access into the portal vein, and tumoral invasion into the portal vein.

Guidance and Technique

Multiple different approaches and techniques have been described for PVE. Historically, PVE was performed through an intraoperative transileocolic approach. Currently, the most commonly used approach is the percutaneous ipsilateral approach. This approach is favored over the contralateral approach because of the avoidance of potential damage to the FLR during access and catheter manipulation. However, if there is no safe route through the ipsilateral liver because of tumor burden, a contralateral approach remains an acceptable alternative. With use of either conscious sedation or general anesthesia, a peripheral branch of the portal venous system to be embolized, most commonly the right, is accessed with a micropuncture needle under ultrasound guidance. Once access is secured, portal venography is performed, and the portal venous system is embolized, depending on the planned surgery. Most commonly, this involves embolizing segments V to VIII of the liver for a right hepatectomy. For an extended right hepatectomy, some authors have advocated embolizing segment IV as well to obtain a greater hypertrophy rate in segments II and III, although the risk of nontarget embolization to the FLR is theoretically greater.¹⁰⁴ The choice of embolic agent is at the discretion of the operator and includes *n*-butyl cyanoacrylate mixed with Lipiodol and polyvinyl alcohol particles or gelatin sponge and coils. A meta-analysis suggested that the use of *n*-butyl cyanoacrylate results in a higher percentage of FLR volume increase.⁹⁹ After embolization is complete, the sheath track is embolized with either gelatin sponge or coils.

Results and Complications

Technical success rates of PVE are approximately 99%. Most technical failures result from an inability to cannulate the portal system because of altered anatomy or unexpected thrombosis of the portal system due to tumor progression or invasion.⁹⁹ After embolization, follow-up CT is performed at 4 weeks for recalculation of the FLR as liver regeneration tends to plateau

after 3 weeks.⁹⁸ The clinical success rate (defined as sufficient FLR hypertrophy to allow resection) is 96.1% with a mean increase in the FLR volume of 37.9%, with a range of 20.5% to 69.4%⁹⁹ (Fig. 84-7). However, approximately 20% of patients do not undergo the originally planned liver resection secondary to local intrahepatic tumor progression, new tumor in the FLR, extrahepatic tumor spread, insufficient hypertrophy of the FLR, complications of PVE leading to nonresectability, or refusal of the patient for further treatment. Some select patients may benefit from combination treatment with either transarterial or ablative treatments to achieve curative resection.

Minor complications, including postembolization syndrome consisting of fevers and abdominal pain, occur in 25% to 35% of patients. Transient elevation of liver transaminases is seen in 37% of patients. Major complications, such as portal thrombosis, embolization of nontarget vessels, intraperitoneal hemorrhage or liver hematoma, abscess, and intraperitoneal bile leakage, are rare, occurring in less than 1% of patients.⁹⁹

TUMOR ABLATION

Image-guided ablation therapy of hepatic tumors is a rapidly growing aspect of the field of interventional oncology. Whereas there are many new technologies with relatively few outcomes data, the focus of this discussion is primarily on the most widely used techniques, RF and MW ablation.

Chemical Ablation

Chemical ablation has long been used percutaneously for the treatment of HCC and has the longest clinical follow-up studies of any percutaneous ablation technique. Absolute ethanol is the most commonly used agent, although the use of acetic acid has been described. Ethanol is percutaneously injected into the hepatic tumor and results in tumor destruction by both coagulation and ischemic necrosis. Chemical ablation is most effective for small tumors (<2 cm) and often requires repeated treatments for complete tumor treatment. Ethanol ablation is more effective for treatment of HCC than for metastatic disease, presumably because the tumor capsule or pseudocapsule typical of many HCCs prevents diffusion of ethanol into surrounding parenchyma. In addition, diffusion of ethanol in cirrhotic liver is limited. Studies have demonstrated the superiority of thermal ablation techniques over ethanol for complete tumor destruction. Ethanol is currently reserved for cases in which thermal ablation is contraindicated because of the proximity of adjacent vulnerable structures or in developing countries where cost is the most important selection criterion. Chemical ablation is not recommended for metastatic disease.¹⁰⁵

Thermal Ablation

Cryoablation. Cryoablation involves placement of cryoprobes into a tumor to induce freeze-thaw cycles. Argon gas is the most common cryogen in modern cryoablation systems. The mechanism of cell death is primarily cellular membrane disruption, but tissue ischemia and direct damage to intracellular organelles are also present. After initial enthusiasm, cryoablation is less frequently used to treat malignant hepatic tumors because of the lengthy ablation cycles, the lack of ability to cauterize the applicator track (increasing the risk of hemorrhage), a risk of hepatic fracture, and the risk of multiorgan failure termed cryoshock, particularly in cirrhotics.¹⁰⁶

Figure 84-7 Portal vein embolization. **A.** CT examination in a patient with metastatic colorectal cancer performed in preparation for extended right hepatectomy demonstrates a small future liver remnant (segments I-III). CT volumetry was performed, and a future liver remnant (FLR)/total liver volume (TLV) ratio was calculated at 15.2%, precluding planned surgical resection. **B** and **C.** Fluoroscopic images before and after portal vein embolization through a right-sided approach with particles and coils demonstrate complete devascularization of the right hemiliver. Follow-up CT examination performed 4 weeks after portal vein embolization demonstrates significant hypertrophy of the FLR. **D.** CT volumetry after embolization demonstrated an FLR/TLV ratio of 23.8% with a 62.9% increase in the FLR. The patient underwent the planned extended right hemihepatectomy. **E.** Follow-up CT examination performed 2 years after surgery demonstrates significant hypertrophy of the liver remnant without recurrent disease.

Radiofrequency Ablation. Heat-based ablation techniques can result in coagulation necrosis when tissue is heated to a temperature threshold for a specific time. Tissue heating to 50°C for approximately 5 minutes typically results in cell death, whereas temperatures above 60°C cause cell death within seconds. RF ablation is currently the most frequently used thermal ablation technique in the treatment of hepatic tumors. In monopolar RF systems, a generator is used to create alternating electrical current that oscillates between the electrode placed in the tumor and grounding pads, resulting in cellular agitation and tissue heating. Standard electrodes include single-needle or multiple-needle arrays (sometimes

cooled to prevent charring) and multiple tines emanating from one needle. Multiple tines improve heating efficiency and energy deposition but typically require larger diameter, more invasive needles. Multiple-probe RF systems are now available that take advantage of thermal synergy to create larger and more confluent ablation zones. However, because of electrical interactions between simultaneously activated electrodes, a switching system is necessary.¹⁰⁷ In bipolar RF systems, two electrodes are placed within or adjacent to the tumor and current oscillates between them, without the need for grounding pads. In all RF configurations, saline can be instilled to decrease charring and to reduce impedance, thus

resulting in more energy deposition but potentially less control of the ablation zone.¹⁰⁵

Microwave Ablation. MW ablation technology is based on tissue heating by dielectric hysteresis, requiring molecules with an intrinsic dipole moment to continuously realign with an applied field, resulting in increased kinetic energy and tissue heating. MW technology has multiple advantages over RF ablation. Because MW energy readily penetrates even those tissues with high impedance (such as charred tissues), it can be applied at much higher temperatures than RF energy. MW ablation does not require grounding pads, and multiple antennas can be used simultaneously without switching to create both electrical and thermal synergy. Despite these advantages, MW energy is a more complicated technology to apply in tissue. For example, reflected power at the tissue-antenna interface can cause antenna shaft heating and result in thermal injury along the puncture track. More recent MW systems use a cooling jacket with circulating water or gas to obviate this problem. To date, MW ablation technology has been used most extensively in Asia, although it is becoming much more frequently used worldwide.¹⁰⁵

In general, RF technology suffers in areas of high blood flow because of the heat sink effect and also struggles in tissues with high impedance because of decreased power distribution. MW technology is faster, more efficient, less sensitive to heat sink effect, and not sensitive to differences in tissue impedance. Despite being less well studied than RF technology, early clinical results demonstrate that MW is at least as effective as RF ablation, resulting in rapid replacement of RF because of the overall physical advantages listed before.¹⁰⁵

Indications

HCC is the most common indication worldwide for hepatic tumor ablation. The treatment strategy of HCC is generally shaped by the Barcelona Clinic Liver Cancer (BCLC) guidelines.^{19,108} Although studies have shown that surgical tumor resection provides the best survival outcome, only 20% of patients are resection candidates, generally defined as patients without portal hypertension and with a normal bilirubin level. Liver transplantation is also a curative treatment for patients with HCC. However, orthotopic liver transplantation is often available only for patients who meet Milan criteria (up to three tumors smaller than 3 cm or one tumor larger than 5 cm) and is limited by organ availability.¹⁰⁹ For those patients who are not resection candidates because of poor hepatic function and who are poor transplantation candidates, tumor ablation is a potentially curative alternative therapy. Ablation is also used as a bridge to transplantation in the setting of either local tumor control during the waiting period for liver transplantation or downstaging the tumor so that the patient meets Milan criteria. Although there have been some excellent results with downstaging into Milan criteria, this remains a controversial topic because of the limited number of donor livers available and the large numbers of patients on the waiting list.¹¹⁰⁻¹¹²

The second most common indication for liver tumor ablation is unresectable colorectal cancer metastasis. In general, surgical resection is first-line therapy for hepatic colorectal metastatic disease in eligible patients. However, many patients are not resection candidates because of comorbidities, recent surgery, or anatomic considerations. Percutaneous ablation can often achieve excellent local tumor control, particularly for

tumors smaller than 3 cm.^{113,114} Patients who are not resection or ablation candidates because of either the location or the number of metastases are typically treated with either TACE/radioembolization or systemic chemotherapy.

Although less well studied, tumor ablation has also been used for hepatic metastatic disease from sites other than colorectal primary tumors, including breast, renal cell, and neuroendocrine primary tumors, for both local disease control and symptomatic relief in patients who are not surgical candidates.¹¹⁵⁻¹¹⁸ Both RF ablation and MW ablation have also been used successfully to treat benign hepatic tumors, such as symptomatic hepatic hemangiomas.¹¹⁹

Contraindications

Patients with severe liver failure are poor ablation candidates for fear of worsening hepatic function. Tumors close to vital structures, such as main portal venous branches, large segmental bile ducts, gallbladder, and bowel, may not be amenable to percutaneous ablation. However, nontarget structures such as the gallbladder, diaphragm, and bowel can often be displaced by hydrodissection, and many tumors can then be successfully treated.^{120,121} Uncorrectable coagulopathies have traditionally been considered contraindications to tumor ablation. With the ability to perform intraprocedural cautery with heat-based ablation, many centers are adopting more liberal coagulation parameter guidelines. Extrahepatic metastatic disease is typically a contraindication to ablation therapy unless the goal is tumor debulking in the setting of an indolent malignant neoplasm.¹⁰⁶ Finally, 40% to 50% of patients who have undergone prior biliary sphincterotomy or surgery will develop a postablation abscess, despite prophylactic antibiotic therapy.¹²²

Coagulation parameters should be evaluated before hepatic tumor ablation is performed. The most widely accepted guidelines suggest that the patient have an INR below 1.5 and a platelet count of more than 50,000/ μ L before undergoing percutaneous hepatic tumor ablation.¹²³ Anticoagulant and antiplatelet medication therapies are typically held for 5 to 7 days before the procedure, although the risk of complications from withholding of these medications must also be considered, particularly in patients with recently placed coronary artery stents.

Guidance and Technique

Most hepatic tumor ablation procedures are performed under general anesthesia, given the pain resulting from tissue heating. General anesthesia also provides for more reliable breath holding, which is essential for accurate probe placement. Continuous sonographic guidance is most frequently used for both probe placement and monitoring of the ablation zone, although CT guidance is occasionally necessary for lesions that are sonographically occult. At the completion of the ablation procedure, many centers elect to perform a contrast-enhanced CT examination to ensure that the ablation zone appropriately encompasses the tumor (Fig. 84-8). Whereas a margin of 5 mm is acceptable for HCC, margins of at least 1 cm are suggested for hepatic metastases because of the high prevalence of metastatic tumor cells beyond the visible tumor margin.^{124,125}

Fluid injected into the peritoneal space (artificial ascites) or other body cavities can be used to decrease postprocedural body wall pain or to displace bowel or other nontarget collateral organs.^{120,121,126} Dextrose in water is the preferred fluid for use with RF ablation as the nonionic nature prevents electrical current conduction. Saline is an ionic medium that allows the

Figure 84-8 Microwave ablation of HCC.

Biphasic CT demonstrates an arterially enhancing left hepatic lobe lesion (**A**) with central portal venous washout (**B**) in a cirrhotic patient who met imaging OPTN criteria for HCC. Subsequent ultrasound demonstrates placement of two microwave antennas into the hypoechoic lesion (**C**), with gas covering the lesion during the ablation (**D**). **E**. Postablation CT demonstrates no evidence of residual enhancement; the effect of cautery along the track of the ablation antennas is readily visible.

propagation of electricity. Either fluid is acceptable for use with MW ablation. Iodinated contrast material can be added to any fluid for improved visualization on intraprocedural CT.¹²⁷

Results

HCC. The results after treatment of HCC with RF or MW ablation are dependent primarily on tumor diameter. Treatment of tumors smaller than 3 cm is associated with excellent local tumor control, with survival equivalent to that of surgical resection.¹²⁸⁻¹³⁰ Local tumor control decreases for tumors larger than 3 cm. Recent work exploring the combination thermal ablation and intra-arterial therapies (such as TACE) demonstrates promising results for local control for intermediate-size tumors (3-5 cm in diameter).¹³¹ Local therapy must be performed with the understanding that it is not only HCC but also the patient's underlying liver disease that is life limiting. Many patients die of underlying liver failure rather than of HCC.

Metastatic Disease. Survival after treatment of metastases with RF ablation is superior to that with chemotherapy alone but

may be slightly worse than with liver resection. However, no randomized controlled trials have been performed comparing ablation and resection for patients who are candidates for either treatment, and most ablation series include patients who are not surgical candidates with substantial comorbidities.^{132,133} Similar to the results with HCC, smaller tumors (<3-4 cm) are associated with lower local tumor progression than larger tumors. Survival after RF ablation of colorectal liver metastases ranges from 91% to 93% at 1 year, 28% to 69% at 3 years, and 25% to 46% at 5 years.¹³⁴⁻¹³⁶

Complications

Mortality rates after hepatic tumor ablation are low and range from 0.1% to 0.5%, most commonly resulting from liver failure, sepsis, or portal venous thrombus. Major complications are seen in approximately 2% to 3% and include hemorrhage, hepatic abscess, liver failure, and bile duct injury. As mentioned previously, patients who have undergone prior biliary sphincterotomy or stent placement are at much higher risk of hepatic abscess formation after the procedure. Tumor applicator track

seeding is uncommon but can be an important complication in the setting of HCC. The incidence of track seeding varies, but a median risk is approximately 0.6% after HCC ablation.^{137,138} When tumor does seed along the ablation track, it should have the same enhancement characteristics as the primary tumor. Either follow-up imaging or biopsy is necessary to differentiate between postablation inflammatory soft tissue and applicator track seeding.¹³⁹

Postablation syndrome is manifested by influenza-like symptoms beginning 48 hours after the procedure, generally resolving by 7 days after the procedure. Although uncomfortable, it is generally not a serious complication and can be managed with anti-inflammatory medications and supportive care. Cryoshock can be a severe complication related to release of intracellular contents into the circulation, which can result in disseminated intravascular coagulation, hepatic and renal failure, and death.¹³⁸ This syndrome is seen almost exclusively in cirrhotic patients treated with cryoablation.

Follow-up

The timing of follow-up imaging examinations is specific to individual institutions, but follow-up scans should be performed several times in the first year after ablation to evaluate for local tumor progression, development of new disease, and postablation complications. CT and MRI are the most common methods of imaging follow-up, although positron emission tomography (PET)/CT has been shown to be useful for certain tumors. CT or MRI performed 1 to 3 months after ablation typically demonstrates a nonenhancing ablation zone, usually larger than the original tumor because of the ablative margin. A thin rim of peripheral enhancement is commonly seen secondary to inflammation or hyperemia and should not be misconstrued as local tumor progression. The central ablation zone will demonstrate a high-attenuation T1 hyperintense center corresponding to desiccated tissues and blood products. The ablation zone should progressively decrease in size during 6 to 12 months but may remain visible for several years. If track cautery was used during withdrawal of the ablation applicator, the track is often seen with characteristics similar to those of the ablation zone.¹⁴⁰ Local tumor progression, if present, will generally be seen as irregular nodular enhancement at the periphery of the ablation zone and will have imaging findings similar to residual disease. MRI is typically more sensitive than CT in identifying residual disease or local progression. Residual tumor at MRI demonstrates T2 hyperintensity (in contrast to the T2 hypointensity of the ablation zone). Diffusion-weighted images can be helpful to identify small residual tumor nodules.¹⁴¹

A variety of postablation complications are possible. Biliary duct injury typically is manifested with focal biliary ductal dilation due to a more central stricture. Bilomas are also possible. Gallbladder injury is manifested with gallbladder wall thickening and pericholecystic fluid. Hepatic abscess is common after ablation in patients with previous biliary manipulation and is manifested as enlargement of the ablation zone or an intrahepatic collection. Gas is common within the ablation zone immediately after the procedure, but if the amount of gas increases on subsequent examinations, this is concerning for ablation zone infection. Bowel injury is manifested with focal bowel wall thickening and mucosal hyperenhancement. Finally, the hepatic vasculature should be evaluated on follow-up imaging as portal vein thrombosis, hepatic arterial

pseudoaneurysm, and hepatic infarction have been reported¹⁴¹ (Fig. 84-9).

ENDOVASCULAR INTRA-ARTERIAL THERAPIES

Transcatheter intra-arterial therapies have been developed for the treatment of both primary and secondary hepatic malignant neoplasms. The goal of intra-arterial therapy is to selectively deliver anticancer treatment to tumors with the hope of achieving reduced toxicity profiles and tumor response. The basis for intra-arterial therapy of liver tumors stems from the dual blood supply to the liver. Hepatic neoplasms preferentially receive most of their blood flow from the hepatic arterial system, whereas normal liver parenchyma derives approximately 70% of its blood flow from the portal vein. This duality allows catheter-based therapies such as transarterial embolization, hepatic intra-arterial chemoinfusion, TACE and DEB-TACE, and transarterial radioembolization to selectively target tumors and to spare normal parenchyma.

Transarterial Chemoembolization

Brief Rationale. TACE with the use of anticancer drugs followed by Gelfoam embolization for unresectable HCC was introduced in the late 1970s by Yamada and associates.¹⁴² TACE is defined as the infusion of a mixture of chemotherapeutic agents with or without iodized oil followed by embolization with particles. The goal of chemoembolization is to expose tumors to high concentrations of a local chemotherapeutic agent in a hypoxic environment with minimal systemic drug bioavailability. Ischemia induced by embolization may result in failure of transmembrane pumps, thus allowing increased absorption of the agents by the cells with decreased washout.

There is no consensus on the type or concentration of chemotherapeutic agents used in TACE. The most common multidrug combination used in the United States is a mixture of mitomycin C, doxorubicin, and cisplatin. Doxorubicin is the most commonly used single-agent regimen worldwide. Regardless of the chemotherapeutic regimen, the drugs are emulsified in Lipiodol, an oily contrast agent that acts as a carrier of the chemotherapeutic agents and accumulates selectively within the neovasculature and extravascular spaces of liver tumors.^{143,144} Multiple different agents have also been used for embolization of the target vessel after infusion of the Lipiodol chemotherapeutic agent mixture, including absorbable gelatin sponge, polyvinyl alcohol particles, and trisacryl gelatin microspheres.

Indications and Contraindications. The indications for TACE for HCC have become more standardized as described before. Currently, TACE is recommended for unresectable intermediate-stage HCC (BCLC stage B or Child-Pugh class A/B with large or multifocal HCC and no vascular invasion or extrahepatic spread).^{19,108} It has recently been reported that TACE may also be safely performed in select patients with portal vein thrombosis with no increase in morbidity or mortality.^{145,146} TACE may also be considered in combination therapies with ablation, in patients with recurrence after curative therapy, and in potential transplant recipients to avoid progression of disease and subsequent removal from the transplant waiting list. TACE has also demonstrated an effective role for the palliative treatment of multiple hepatic malignant neoplasms, including cholangiocarcinoma as well as neuroendocrine, colorectal, uveal melanoma, and breast metastases.¹⁴⁷⁻¹⁵² General exclusion criteria

Figure 84-9 Portal vein thrombosis after microwave ablation. **A.** Portal venous phase CT demonstrates an exophytic lesion arising from the caudate lobe that met imaging criteria for HCC, which underwent percutaneous microwave ablation. **B.** Subsequent CT demonstrates the immediate postablation appearance. **C.** CT performed at 1 month after the procedure demonstrates nonocclusive portal venous thrombus, a complication of the ablation procedure. **D.** The patient was prescribed warfarin and the thrombus resolved, as seen on the CT performed at 1 year after the procedure.

for TACE have not been well defined. Multiple factors are associated with increased periprocedure mortality, including the combination of elevated bilirubin levels above 2 mg/dL, more than 50% tumor burden, lactate dehydrogenase levels greater than 425 mg/dL, and aspartate aminotransferase levels greater than 100 IU/L.¹⁵³ Child-Pugh class C liver disease, elevated bilirubin levels above 3 mg/dL, and elevated MELD (>10) or CLIP (>2) scores also are relative contraindications.¹⁵⁴

Guidance and Technique. After proper patient selection based on imaging and clinical findings, TACE is performed with standard endovascular techniques. Review of preoperative imaging is imperative for comprehensive evaluation of possible variant hepatic arterial anatomy, presence of extrahepatic tumoral blood supply, and portal vein patency. Selective angiography of the celiac and superior mesenteric arteries is performed to assess for variant hepatic arterial anatomy with imaging through the portal venous phase to confirm patency of the portal venous system. Various microcatheters are available for subsequent superselective angiography of the intrahepatic arterial vasculature. TACE can be performed from the subsegmental to the lobar level, depending on the type and number of tumors to be treated. The use of cone-beam CT during TACE procedures has been shown to be associated with

improved survival outcomes, identification of extrahepatic tumoral blood supply, and decreased risk of nontarget chemoembolization.¹⁵⁵ Intermittent infusion of 1% lidocaine between aliquots of the chemotherapy/Ethiodol slurry can decrease postembolization pain. After the procedure, patients are admitted to the hospital for overnight observation and pain control. Some centers recommend antibiotic treatment for 3 to 7 days after TACE to cover gram-negative enteric pathogens, with prolonged treatment of 2 weeks for patients with a disrupted sphincter of Oddi; however, the data regarding this practice are inconclusive.¹⁵⁴ Repeated treatment with TACE for new or residual disease is evaluated on a patient-by-patient basis, with planned consecutive treatments at least 3 weeks apart (Fig. 84-10).

Results

HCC. Multiple large case series have been reported showing the efficacy of conventional TACE for carefully selected patients with HCC. Randomized controlled trials have demonstrated that TACE provides a statistically significant benefit in survival and tumor response over the best supportive care measures.^{156,157} A large systematic review showed survival rates for patients with HCC undergoing TACE after the year 2000 at 1, 3, and 5 years of 71% ± 18%, 34% ± 13%, and 14% ± 10%.¹⁵⁸ Another large

Figure 84-10 Transarterial chemoembolization of HCC.

A. Selective angiography of the left hepatic artery demonstrates a 5-cm hypervascular mass consistent with hepatocellular carcinoma. **B.** Angiogram of the common hepatic artery after transarterial chemoembolization demonstrates no evidence of arterial enhancement within the treated lesion. **C and D.** Follow-up CT examination in the late arterial and portal venous phases demonstrates dense Lipiodol uptake within the left lateral aspect of the lesion (*white arrow*). At the right lateral aspect, there is persistent arterial enhancement and portal venous washout with rim enhancement consistent with residual untreated tumor (*black arrow*).

prospective cohort study of 8510 patients showed an overall median survival of 34 months with 1-, 3-, and 5-year survival rates of 82%, 47%, and 26%, respectively.¹⁵⁹ Currently, studies are investigating the effect of the combination of TACE with systemic molecular targeted therapies such as sorafenib, a multikinase inhibitor with antiangiogenic and antiproliferative effects that has shown survival benefit in patients with advanced HCC. An interim analysis of one of these studies has shown that this combination results in increased tumor response and time to progression.¹⁶⁰

Metastatic Disease and Cholangiocarcinoma. Overall median survival for patients with unresectable intrahepatic cholangiocarcinoma treated with TACE has been reported at 13 months with 1-, 3-, and 5-year survival rates of 52%, 29%, and 10%.¹⁴⁷ Child-Pugh class A liver dysfunction, hypervascular tumors, and initial tumor response were found to be factors associated with statistically significant increase in patient survival. TACE not only has shown a survival benefit in patients with metastatic neuroendocrine disease to the liver but also has a significant symptomatic benefit for patients suffering from carcinoid syndrome, with a symptomatic response rate of 60% to 95% for 20 to 85 months and a 5-year survival of between 50% and 65%. Bland transarterial embolization has shown similar response rates.¹⁴⁸ A median survival time of 9 to 14 months has been reported for patients undergoing TACE for unresectable colorectal liver metastases after failure of standard chemotherapy protocols, with a significant increase in median survival when TACE was implemented after first- or

second-line systemic therapy compared with third- to fifth-line therapies.^{149,150}

Complications. Postembolization syndrome, consisting of transient fever, pain, elevation of hepatic transaminases, and increased white blood cell count, can be seen in 60% to 80% of patients undergoing TACE. This is not considered a complication but rather an expected procedural outcome. The incidence of major complications after TACE ranges from 1% to 7.5%; these include liver failure, abscess, cholecystitis, biloma requiring percutaneous drainage, pulmonary arterial oil embolus, gastrointestinal hemorrhage or ulceration from nontarget embolization, renal dysfunction, and iatrogenic hepatic artery injury preventing treatment. The 30-day mortality after TACE is approximately 1% to 2.5% and has been most commonly reported secondary to acute liver failure but also can be secondary to acute renal failure, upper gastrointestinal bleeding, tumor rupture, and sepsis.¹⁵⁸

Follow-up. Follow-up imaging after TACE is usually performed 4 to 6 weeks after all tumor-bearing areas have been treated; however, some physicians may perform imaging studies between staged bilobar treatments. Assessment of tumor response after TACE is generally based on iodized oil deposition on unenhanced CT and tumor enhancement and size on postcontrast CT or MR images. High concentrations of iodized oil within a lesion after TACE may make assessment of enhancing tumor difficult. MRI may have advantages over CT for assessing tumor

viability after TACE as iodized oil does not affect MR signal intensity.^{161,162} One early study has shown that dual-energy CT can be used to improve evaluation for residual disease after TACE.¹⁶³ Hypovascular tumors, such as cholangiocarcinoma and various metastatic lesions such as breast cancer, may also demonstrate a decrease in overall tumor enhancement after TACE.

Drug-Eluting Bead Chemoembolization

Brief Rationale. Chemoembolization with drug-eluting beads is a recent advance in transarterial oncologic therapies with the goal of enhancing the delivery of potent chemotherapeutic agents to the site of tumor. Chemotherapeutic agents are loaded into polyvinyl alcohol-based microspheres, which allows fixed dosing and controlled and sustained release of the agents locally after embolization. Significant reductions in peak plasma concentrations of chemotherapeutic agents after DEB-TACE compared with conventional TACE have been shown, which may suggest a higher concentration of the drug in the tumoral microenvironment compared with the systemic circulation.^{164,165} This may result in more potent tumoricidal effect with a decrease in systemic side effects. Currently, the two most common chemotherapeutic agents being used for DEB-TACE are doxorubicin for HCC and irinotecan for metastatic colorectal cancer.

Indications and Contraindications. The indications for and contraindications to DEB-TACE in the setting of primary or metastatic liver disease are similar to those reported for conventional TACE.¹⁶⁶

Guidance and Technique. The endovascular approach to DEB-TACE is similar to conventional TACE. The dose of doxorubicin administered during a single treatment for HCC can vary on the basis of individual patient- and tumor-related factors but usually consists of either 75 mg of doxorubicin loaded into one vial of microspheres or 150 mg of doxorubicin loaded into two vials of microspheres.¹⁶⁷ The administered dose of irinotecan for metastatic colorectal cancer usually is 100 mg loaded into one vial of microspheres.¹⁶⁸ The size of microspheres used for DEB-TACE varies; 100- to 300- μ m beads are recommended on the basis of the expected distribution inside the tumor or close to the tumor margin.¹⁶⁹ Loaded microspheres should be mixed with a nonionic contrast medium before injection to aid in visualization during treatment. Similar to conventional TACE, treatment with drug-eluting beads can be performed from a subsegmental to a lobar level, depending on the type and number of tumors to be treated. Injection should be performed at a slow, controlled rate and continued until near stasis is observed or the entire dose has been administered. Meticulous attention to technique should be observed to avoid nontarget extrahepatic embolization. After the procedure, patients are admitted to the hospital for pain control. Repeated treatment with DEB-TACE for bilobar disease can be performed 2 to 4 weeks after the original treatment in the absence of complications, whereas a 4- to 8-week interval for re-treatment is recommended for residual disease.¹⁶⁷

Results. A large, multicenter randomized controlled trial comparing conventional TACE to DEB-TACE with doxorubicin for patients with unresectable HCC in BCLC classes A and B showed no statistically significant differences with respect to

tumor response. However, patients treated with DEB-TACE demonstrated improved tolerability with a statistically significant decrease in serious liver toxicity and a lower rate of doxorubicin-related side effects.¹⁷⁰ A randomized controlled trial comparing DEB-TACE to bland embolization demonstrated a significant difference in time to progression, with lower rates of recurrences and higher rate of complete response at 9 and 12 months.¹⁷¹ Survival rates at 1, 3, and 5 years have been reported at 90% to 94%, 62% to 66%, and 23% to 38%, respectively, for patients with BCLC class A and B disease, with an overall median survival ranging from 44 to 49 months.^{172,173}

The efficacy of DEB-TACE with irinotecan for the treatment of metastatic colorectal cancer refractory to systemic chemotherapy has been reported by a multicenter single-arm study, with overall survival of 19 months and progression-free survival of 11 months.¹⁶⁸

Complications. The incidence of postembolization syndrome with DEB-TACE is similar to that with conventional TACE; mild symptoms are reported in up to 86.5% of patients. Minor complications after DEB-TACE include cholecystitis, pleural effusion, and skin erythema after embolization of extrahepatic collateral vessels, with reported rates of less than 5%. Major complications include acute liver failure, abscess formation, and upper gastrointestinal tract bleeding, with 30-day mortality rates reported from 0% to 3.6%.^{174,175}

Follow-up Imaging. Follow-up imaging protocols are similar to those for conventional TACE. Initial imaging is performed 4 to 6 weeks after treatment with dynamic CT or MRI. Assessment of tumor response is based on size and enhancement characteristics.

Transarterial Radioembolization

Brief Rationale, Indications, and Contraindications. Whole liver external beam radiation therapy has had a limited role in the treatment of both primary and metastatic liver malignant neoplasms because of the relative radiosensitivity of normal hepatic tissue. Radiation-induced hepatitis has been observed in doses exceeding 35 Gy, which is below the estimated tumoricidal dose of 50 to 70 Gy.^{176,177} Transarterial radioembolization has been developed as a method of selectively administering microspheres loaded with a radioisotope, yttrium 90 (⁹⁰Y), into the hepatic arteries supplying the tumor to achieve radiation doses as high as 150 Gy without development of the clinical complications seen with external beam therapy.¹⁷⁷ ⁹⁰Y is a pure beta emitter with a half-life of 64.2 hours that decays to stable zirconium 90. The emissions have a mean tissue penetration of 2.5 mm with a maximum reach of 11 mm. Radioembolization results in localized generation of oxygen free radicals of water molecules near to the tumor cell's DNA. In the presence of normal oxygen tension, permanent DNA damage is caused and results in apoptosis.¹⁷⁶

There are currently two commercially available radioembolic agents. Theraspheres (MDS Nordion, Ottawa, Ontario, Canada) are glass microspheres ranging in diameter from 20 to 30 μ m. SIR-spheres (Sirtex Medical, North Ryde, Australia) are resin microspheres ranging in diameter from 20 to 60 μ m. Radioembolization with ⁹⁰Y has been shown to have clinical benefit in HCC, intrahepatic cholangiocarcinoma, and metastatic disease from colorectal, neuroendocrine, breast, and uveal melanoma primary malignant neoplasms.¹⁷⁸⁻¹⁸⁶ Patients considered for

radioembolization therapy should have unresectable hepatic primary or metastatic cancer with liver-dominant tumor burden and a life expectancy of more than 3 months.¹⁸⁷ Patients presenting with branch portal vein invasion and good liver function may also be considered for radioembolization as hepatic arterial inflow is maintained after treatment.¹⁸⁸ Contraindications to radioembolization therapy include a pretreatment technetium Tc 99m macroaggregated albumin scan demonstrating the potential for 30 Gy or more of radiation exposure to the lung or flow to the gastrointestinal tract that cannot be corrected by catheter embolization techniques, a limited hepatic reserve, a bilirubin level of more than 2 mg/dL without a reversible cause, and a history of prior radiotherapy involving the liver.¹⁸⁷

Guidance and Technique. After careful patient selection, preferably by multidisciplinary consensus involving medical oncology, surgical oncology, radiation oncology, and interventional radiology, treatment with ⁹⁰Y microspheres involves at least a two-stage process. Patients undergo a vascular mapping procedure by standard endovascular techniques to delineate the mesenteric and hepatic arterial blood supply to the intended targeted treatment area and to identify any variant hepatic arterial anatomy that may require separate treatment sessions. Prophylactic embolization of extrahepatic arteries, such as the gastroduodenal and right gastric arteries, may be performed to isolate the hepatic arterial circulation and to decrease the risk of nontarget radioembolization to the gastrointestinal tract. Finally, ^{99m}Tc-macroaggregated albumin is injected with the catheter position and flow rate that mimics the anticipated ⁹⁰Y

injection, with subsequent scintigraphic imaging to evaluate for hepatopulmonary shunting or gastrointestinal tract uptake. The dose of ⁹⁰Y microspheres to be delivered is then calculated on the basis of the chosen particles (glass vs. resin microspheres), the intended treatment volume (whole vs. lobar vs. segmental treatment), and the percentage of pulmonary shunting. The treatment session should take place 1 to 3 weeks after the vascular mapping procedure, and arteriography is performed before ⁹⁰Y microsphere injection to evaluate for revascularization of extrahepatic branches that may result in nontarget radioembolization. If bilobar treatment is planned, the second treatment is usually performed 4 to 6 weeks after the first treatment.

Results. The results of treatment of HCC with ⁹⁰Y microspheres depends on multiple clinical factors including clinical stage at presentation, presence of portal vein thrombosis, performance status, hepatic reserve, and presence of extrahepatic disease. Two large studies demonstrated median survival of 24.4 to 26.9 months for BCLC class A, 16.9 to 17.2 months for BCLC class B, and 7.3 to 10.0 months for BCLC class C.^{178,179} Patients with Child-Pugh class A liver disease and branch portal vein thrombosis demonstrated a median survival of 16.6 months compared with 7.7 months in Child-Pugh class A with main portal vein thrombosis, 6.5 months in Child-Pugh class B with branch portal vein thrombosis, and 4.5 months in Child-Pugh class B with main portal vein thrombosis.¹⁷⁸ Treatment of HCC with ⁹⁰Y microspheres has also been reported as a measure for downstaging patients to more curative therapies, such as ablation, resection, and liver transplantation^{178,179} (Fig. 84-11).

Figure 84-11 HCC with tumor thrombus treated with ⁹⁰Y transarterial radioembolization. **A** and **B**. Portal venous phase MRI demonstrates an infiltrative lesion with central portal venous washout and rim enhancement. Enhancing tumor thrombus (arrow) as well as nonenhancing bland thrombus (arrowhead) is identified in the left main portal vein. **C**. Selective left hepatic angiography demonstrates a hypervascular mass in segment IV. **D**. Intraprocedural CT after direct injection of iodinated contrast material into the left hepatic artery confirms tumor thrombus (arrow) in the left main portal vein. ⁹⁰Y glass microspheres were administered into the left hepatic artery. **E** and **F**. Portal venous phase imaging 3 years after ⁹⁰Y injection demonstrates complete response to therapy, changes of radiation segmentectomy, and a widely patent left portal vein.

Response rates for patients with unresectable intrahepatic cholangiocarcinoma vary significantly on the basis of preprocedure performance status, with a median survival of 18.3 to 29.4 months for patients with Eastern Cooperative Oncology Group (ECOG) 0 performance status compared with 7 to 10 months for ECOG 1 and 3 to 5.1 months for ECOG 2.^{180,181} In the setting of salvage treatment of colorectal metastatic disease after failure of at least three lines of chemotherapy, patients who responded to radioembolization treatment (by imaging or biochemical tumor assay) demonstrated a median survival of 10.5 months compared with 4.5 months for nonresponders and historical controls.¹⁸² With regard to neuroendocrine liver metastases, a large multicenter retrospective series demonstrated stable disease in 22.7%, partial response in 60.5%, complete response in 2.7%, and progressive disease in 4.9%, with an overall median survival of 70 months.¹⁸⁴

Complications. The most common minor complication is postradioembolization syndrome, which can affect 20% to 55% of patients and is characterized by clinical symptoms of fatigue, nausea, vomiting, anorexia, fever, abdominal discomfort, and cachexia.¹⁸⁹ Other potential complications include radiation-induced liver disease (0%-4%); biliary sequelae, such as biliary stricture, necrosis, or radiation cholecystitis (<10%); radiation pneumonitis (<1%); and gastrointestinal ulceration (<4%).¹⁸⁹ The mild adverse events and constitutional symptoms secondary to ⁹⁰Y microsphere radioembolization rarely require hospitalization, whereas the serious adverse events can be mitigated by proper patient selection, appropriate dosimetry methods, and meticulous technique.

Follow-up. Patients are usually followed up clinically 2 weeks after treatment with a review of systems, physical examination, and routine laboratory tests.¹⁸⁷ Routine imaging performed with CT or MRI at 4 to 6 weeks after treatment is common at many centers. Early imaging after ⁹⁰Y microsphere radioembolization often demonstrates hepatic parenchymal edema, and lesions may mildly increase in size but usually show signal intensity or attenuation differences. Assessment of enhancement at early imaging by the modified response evaluation criteria in solid tumors (mRECIST) or the European Association for the Study of the Liver (EASL) criteria correlates with response on follow-up imaging. Full treatment response by size criteria is usually evident by 3 months after treatment with resolution of the acute radiation changes. PET/CT may show earlier decreases in metabolic activity for FDG-avid lesions at 6 weeks after treatment, but PET/CT has limited sensitivity for detecting activity in small lesions.

COMBINATION INTERSTITIAL AND ENDOVASCULAR THERAPY

Ablation and TACE

Brief Rationale and Indications. Ablative therapies for HCC have shown promising results and may be equivalent to surgical resection for some cases, particularly when tumors are smaller than 3 cm.¹⁹⁰ For tumors larger than 3 cm, it is difficult to ablate all viable tumor tissue and to create an adequate tumor-free margin. Also, the presence of satellite nodules is more commonly seen in larger tumors. Combination therapy consisting of TACE followed by ablation has been increasingly used to obtain larger ablation zones and to achieve better local control in patients with tumors larger than 3 cm.¹⁹¹ The synergistic effect of combination therapy results from the occlusion of hepatic arterial flow by embolization, which reduces the cooling effect of hepatic blood flow on thermal coagulation. In addition, Lipiodol fills the peripheral portal veins surrounding the tumor through multiple arteriportal communications and thus reduces portal flow. The tumoricidal effect of anticancer agents is enhanced by hyperthermia, which may result in cell death in marginal areas of the ablation zone that reach sublethal temperatures. Finally, TACE may also help control the small satellite microlesions not encompassed in the ablation zone.

Results. Multiple studies have demonstrated that combination therapy of TACE followed by RF ablation results in significantly lower local tumor progression rates with improved survival rates for tumors larger than 3 cm compared with RF ablation alone.¹⁹²⁻¹⁹⁴ A randomized study comparing combination therapy with RF ablation alone for recurrent HCC also demonstrated significantly decreased local tumor progression rates and improved overall survival at 1, 3, and 5 years for combination therapy compared with RF ablation alone for lesions larger than 3 cm; however, these differences were found not to be significant in patients with recurrences smaller than 3 cm.¹⁹⁵ A randomized study of patients with HCCs smaller than 3 cm also failed to show a benefit of combination therapy compared with RF ablation alone, with equivocal rates of local tumor progression and overall survival at 1, 2, 3, and 4 years.¹⁹⁶ Combination therapy may also prove useful for lesions in anatomically difficult locations (i.e., subcapsular or caudate lobe lesions), residual disease after primary ablation not amenable to re-treatment, and lesions difficult to identify on ultrasound imaging alone.¹⁹⁷⁻²⁰⁰ Complication rates for combination therapy have been reported to be similar to those of the treatments separately without additive effect.

Anomalies and Anatomic Variants of the Liver

ALI SHIRKHODA | RICHARD M. GORE

CHAPTER OUTLINE

Hepatic Embryology

Normal Anatomic Variants

Accessory Fissures and Diaphragmatic Slips

Sliver of Liver

Papillary Process of the Caudate Lobe

Anatomic Anomalies

Riedel's Lobe

Pedunculated Accessory Hepatic Lobes

Agenesis and Hypoplasia of the Right Hepatic Lobe

Agenesis and Hypoplasia of the Left Hepatic Lobe

The diagnostic pitfalls in cross-sectional imaging studies of the liver include variants of normal anatomy, developmental anomalies, and postsurgical changes. Others are often related to intravenous contrast material and scanning at various hepatic phases. This chapter focuses on anatomic variants and anomalies and describes how they can be recognized because they may simulate pathologic processes.

Whereas congenital abnormalities of human liver are rare, hepatic anatomic variants are relatively common and represent normal interindividual variation of liver morphology. Such variants include diaphragmatic slips, “sliver of liver” (a leftward extension of the lateral segment of the left lobe), and variants related to the papillary process of the caudate lobe.

There are many kinds of congenital hepatic abnormalities that result from disturbed development of the liver. There are many variations of the hepatic vascular anatomy that may affect liver morphology.¹⁻³ The anomalies that result from excessive development of hepatic tissue occur as a lobar anomaly and include Riedel's lobe as well as other accessory lobes. Those resulting from defective development of the liver include agenesis, hypoplasia, and aplasia of the right or left hepatic lobes. Agenesis refers to complete absence of a lobe, whereas hypoplasia represents a small hepatic lobe that is diminutive but otherwise normal. Aplasia is defined as a small lobe that is structurally abnormal and contains abundant connective tissue, scattered hepatic parenchyma, numerous bile ducts, and abnormal blood vessels.^{4,5}

The position and orientation of the liver may also be altered during embryologic development, resulting in situs inversus, situs ambiguus, and liver herniation. Bipartite liver is extremely rare and occurs when the right and left hepatic lobes are in their respective upper quadrants and are connected by a bridge of tissue.

Hepatic Embryology

During the third week of fetal life, the liver primordium appears as an outgrowth of endodermal epithelium at the distal end of the foregut. This outgrowth, known as the hepatic diverticulum or liver bud, consists of rapidly proliferating cell strands that penetrate the septum transversum, which is the mesodermal plate between the primitive heart and the stalk of the yolk sac. While the hepatic cell strands continue to penetrate into the septum transversum, the connection between the hepatic diverticulum and the distal foregut narrows, thus forming the bile duct.

With further development, the epithelial liver cords intermingle with the vitelline and umbilical veins, forming the hepatic sinusoids (Fig. 85-1). The liver cords differentiate in the hepatocytes and form the lining of the biliary ducts. The Kupffer cells and connective tissue cells of the liver are derived from the mesoderm of the septum transversum.⁶

Normal Anatomic Variants

ACCESSORY FISSURES AND DIAPHRAGMATIC SLIPS

The two main fissures of the liver are the fissures for the falciform ligament and the ligamentum venosum. However, the liver may also contain accessory and pseudoaccessory fissures. True accessory fissures are rare and are the result of an inward folding of the peritoneum, usually involving the undersurface of the liver. The most common one is the inferior accessory fissure, which divides the posterior segment of the right hepatic lobe into lateral and medial portions.⁷⁻¹⁰

Pseudoaccessory fissures are common anatomic variants that result from invaginations of diaphragmatic muscle fibers, usually along the superior surface of the liver (Fig. 85-2). They are more frequently seen involving the right hepatic lobe, but they can occur on the left as well.⁶ These infoldings of the diaphragm often seen in elderly patients can give the liver a scalloped or a lobular appearance and should not be mistaken for macronodular liver in cirrhosis. They can also be a cause of hypodense peripheral pseudomasses on CT (Fig. 85-3). On ultrasound, they may occasionally appear as an echogenic focus in one plane; however, on scanning in the orthogonal plane, the true linear morphology of a fissure is revealed.

SLIVER OF LIVER

Leftward extension of the lateral segment of the left hepatic lobe is referred to as sliver of the liver. It is a common anatomic variant and appears as a crescentic density that wraps around

Figure 85-1 Embryonic development of the liver, pancreas, extrahepatic biliary apparatus, and duodenum. Appearance at 4 weeks (A), 5 weeks (B and C), and 6 weeks (D). (A–D from Gray SW, Skandalakis JE: *Embryology for Surgeons*. Philadelphia, WB Saunders, 1972.)

Figure 85-2 Diaphragmatic invagination in the liver. As a result of invagination of the diaphragmatic slips along the superior aspect of the liver, pseudoaccessory fissures are formed.

the spleen (Fig. 85-4) and may lie lateral, medial, and even posterior to the spleen. It is important not to confuse this variant with either perisplenic or perigastric disease. On ultrasound, this variant can mimic perisplenic hypoechoic collections, and the correct diagnosis is achieved by using color Doppler imaging and documenting continuity with the remainder of the left hepatic lobe.^{7,11}

PAPILLARY PROCESS OF THE CAUDATE LOBE

The caudate lobe is a portion of the liver that extends medially from the right lobe between the inferior vena cava and the fissure for the ligamentum venosum. On occasion, it is divided into two processes. The anterior medial extension of the caudate lobe is known as the papillary process, which extends anteriorly and to the left in the region of the lesser sac. The posterior extension is referred to as the caudate process. Below the porta hepatis, this papillary process can appear separate from the caudate process by a cleft in its inferior margin and can mimic a periportal node or a mass near the head of the pancreas or near the inferior vena cava^{6,7} (Fig. 85-5). However, on multidetector computed tomography (CT) and by use of multiplanar reformation, this anatomic variant is easily recognizable.

Anatomic Anomalies

RIEDEL'S LOBE

Described by Bernhard Moritz Carl Ludwig Riedel, a German surgeon (1846-1916), Riedel's lobe is the most common accessory lobe of the liver, and it is seen most frequently in asthenic women. It is a tongue-like projection from the anterior aspect of the right lobe of the liver that can extend quite inferiorly in some patients. It usually extends along the right paracolic gutter into the iliac fossa (Fig. 85-6) and can be 20 cm or more in length. On physical examination, this anomaly can be mistaken for an enlarged liver or a right renal mass. Riedel's lobe may be connected to the liver by a pedicle consisting of hepatic

Figure 85-3 Diaphragmatic invagination mimicking hepatic nodule. As a result of diaphragmatic invagination, a small, round, low-density mass (arrows) may be suspected in the right hepatic lobe.

Figure 85-4 Sliver of liver. The T2-weighted image of the upper abdomen reveals leftward lateral extension of the left lobe of the liver, which appears as a crescentic low-intensity structure wrapping around the lateral aspect of the spleen.

parenchyma or fibrous tissue. It is usually asymptomatic and is discovered incidentally; however, it may be complicated by torsion with gangrenous changes.⁵ On occasion, the left lobe can behave like a Riedel lobe and extend inferiorly in the abdomen.⁷

PEDUNCULATED ACCESSORY HEPATIC LOBES

Accessory lobe of the liver is an uncommon anatomic variation that is usually asymptomatic. In this condition, the liver tissue is in communication with the main liver (Fig. 85-7), whereas in ectopic liver, the liver tissue lies in the vicinity of the liver without communication with the liver. When an accessory lobe loses its continuity with the liver, it becomes an ectopic liver nodule, which may be attached to the gallbladder, umbilical cord, or pancreas or may lie within the gastrohepatic ligament or thoracic cavity. Ectopic liver has a higher incidence of malignancy.¹² Sato and coworkers,¹³ in a series of 1800 laparoscopic studies, found congenital anomalies of the liver in 19% of the cases, with the incidence of ectopic liver lobe and accessory liver lobe being 0.7%. Other anomalies that were found in this study included fissure formation with anomalous lobation in

4.3%, lobar fusion in 0.5%, left deviation of the round ligament in 3.6%, and high insertion of the round ligament in 2.8%. The accessory lobe is composed of normal hepatic tissue and contains its own hepatic blood vessels and bile ducts. It is connected to the rest of the liver by either normal hepatic parenchyma or a mesentery^{13,14} (see Fig. 85-7). Most accessory lobes are attached to the inferior surface of the liver and have been found in the vicinity of several anatomic sites, including the gallbladder fossa, gastrohepatic ligament, umbilicus, adrenal gland, pancreas, esophagus, and rarely the thoracic cavity. These accessory lobes, particularly when the liver is infiltrated by fat, may be spared and therefore can occasionally mimic masses or adenopathy in these regions.¹⁵ Multiplanar reconstruction and review of continuous thin-slice images are often the key to their diagnosis.

Although most accessory lobes of the liver are asymptomatic, some are pedunculated and suspended from a mesentery that may undergo torsion,¹⁶⁻¹⁸ causing both acute and recurrent abdominal pain. There is an increased incidence of accessory lobes in patients with abdominal wall defects, such as omphalocele.

AGENESIS AND HYPOPLASIA OF THE RIGHT HEPATIC LOBE

Agenesis and hypoplasia of the right lobe of the liver are rare entities diagnosed by noting absence or hypoplasia of liver tissue to the right of the main interlobar fissure.¹⁹⁻²¹ This disorder is thought to be a developmental abnormality that results from either failure of the right portal vein to develop or an error in the mutual induction between the septum transversum (primitive liver).^{21,22} This entity is usually seen in asymptomatic individuals and is discovered incidentally when imaging studies are being performed for unrelated reasons (Fig. 85-8). On occasion, a segment such as an anterior segment of the right lobe may be absent. Postnecrotic cirrhosis, biliary obstruction, and venous occlusive disease have been associated with atrophy or hypoplasia of a hepatic lobe or segment and should be differentiated from congenital absence or hypoplasia.¹⁹

Agenesis of the right lobe of the liver alters the normal anatomy of the upper abdomen. This is due in part to absence of the right lobe as well as to compensatory hypertrophy of the left lobe. Colonic interposition, high position of the

Figure 85-5 Papillary and caudate process pseudomass. **A** and **B.** The T1-weighted fat suppression images reveal medial extension of the papillary process near the head of the pancreas. Notice that the signal characteristics of this mass are similar to the remainder of the liver and not to the pancreas. **C** and **D.** Contrast-enhanced CT scan of the upper abdomen in a different patient reveals inferior extension of an enlarged caudate process mimicking a mass anterior and lateral to the inferior vena cava.

Figure 85-6 Riedel's lobe. Coronal reformatted CT scan displays an elongated inferior extension of the right lobe of the liver (arrows) characteristic of Riedel's lobe.

right kidney, ectopy of the gallbladder (which can be suprahepatic, subdiaphragmatic, or infrahepatic in location), and U- or hammock-shaped stomach can be seen in individuals with agenesis of the right lobe. The caudate lobe may be absent, normal, or hypertrophied.²²⁻²⁴ This entity may also be associated with partial or complete absence of the right hemidiaphragm, intestinal malrotation, choledochal cysts, and agenesis of the gallbladder. Other, more common conditions

can mimic agenesis of the right lobe of the liver, including cirrhosis, atrophy secondary to biliary obstruction, hepatic surgery (Fig. 85-9), and trauma.²⁵ A careful clinical history as well as any associated imaging findings will help to arrive at the correct diagnosis.^{22,26}

Even though a retrohepatic gallbladder and a severely distorted hepatic appearance due to compensatory hypertrophy of the left and caudate lobes may suggest agenesis of the right lobe

Figure 85-7 Pedunculated accessory hepatic lobes. **A.** Frontal (1) and caudal (2) diagrams depict a variety of pedunculated hepatic lobulations (a-f). **B.** They are usually asymptomatic unless they obstruct the gut with their pedicle (p). vf, Gallbladder. **C.** Axial image of the contrast-enhanced CT scan reveals pedunculated accessory left hepatic lobe that mimics a mass in the gastrohepatic ligament. (**A** and **B** from Champetier J, Yver R, Letoublon C, et al: A general review of anomalies of hepatic morphology and their clinical implications. *Anat Clin* 7:285-299, 1985.)

Figure 85-8 Atrophic right lobe of the liver. **A** and **B.** Contrast-enhanced CT study of the upper abdomen reveals atrophy of the right lobe with hypertrophy of the left lobe and prominence of the caudate lobe. Notice that there is only a left portal vein opacified. The fissure for the ligamentum venosum is seen anterior to the caudate lobe.

Figure 85-9 Post-right hepatic lobectomy. **A** and **B.** Hypertrophy of the medial and lateral segments of the left lobe and the caudate lobe is seen in this patient who has total right hepatic lobectomy for metastatic colon carcinoma. Notice marked deviation of the left hepatic lobe to the right upper quadrant.

Figure 85-10 Agenesis of the right hepatic lobe. **A.** CT reveals agenesis of the right lobe of the liver with compensatory hypertrophy of the left lobe. **B.** On a more inferior image, only the left lobe of the liver is identified. The colon occupies the bed of the right hepatic lobe.

of the liver (Fig. 85-10), absence of visualization of all of the right hepatic vein, right portal vein and its branches, and occasionally dilated left intrahepatic ducts is a prerequisite for the diagnosis of agenesis of the right hepatic lobe on CT. In severe lobar atrophy, at least one of these structures is recognizable.¹⁹

AGENESIS AND HYPOPLASIA OF THE LEFT HEPATIC LOBE

Agenesis and hypoplasia of the left hepatic lobe are rare but slightly more common than the right-sided anomalies; however, these are still rare occurrences.²⁷ The diagnosis is made by noting absence or hypoplasia of liver tissue to the left of the main interlobar fissure. Failure to visualize the falciform ligament or ligamentum teres is supportive evidence of agenesis (Fig. 85-11). This disorder is believed to result from the extension of the obliterative process that closes the ductus venosus to the left branch of the portal vein.

Hann and colleagues²⁸ described 13 cases of hepatic lobar atrophy that were evaluated for vascular patency and bile duct obstruction. Hepatic lobar atrophy usually occurs in the setting of combined biliary and portal vein obstruction. A correlation exists between lobar atrophy and ipsilateral portal vein obstruction. Ishida and associates²⁹ reported six cases of lobar atrophy

and investigated the relationship between lobar atrophy and portal flow disturbance. In their report, atrophy of the right lobe was always associated with marked enlargement of the left lobe, but obstruction of flow to the left lobe did not universally result in hypertrophy of the right lobe. As in agenesis of the right lobe of the liver, left lobe agenesis is usually asymptomatic and is discovered incidentally when imaging studies are being performed for other unrelated reasons.^{22,27}

Agenesis of the left lobe of the liver also alters the normal topography of the upper abdomen.²⁷ The stomach and splenic flexure of the colon migrate superiorly and medially to fill the area normally occupied by the left hepatic lobe (Fig. 85-12). Associated findings include a high position of the duodenal bulb, a U-shaped stomach, and a low-lying hepatic flexure of the colon secondary to compensatory hypertrophy of the right lobe of the liver.^{22,30} This anomaly may also be associated with partial or complete absence of the left hemidiaphragm and gastric volvulus.

Before a diagnosis of agenesis of the left lobe of the liver is made, it is important to exclude other causes of acquired atrophy of the left hepatic lobe, such as cirrhosis, malignant disease, malnutrition, or rarely vascular compromise.^{31,32} In these disorders, at least some liver tissue is found left of the main lobar fissure.³³

Figure 85-11 Agenesis of the left lobe. **A.** In this contrast-enhanced CT study of the upper abdomen, there is total agenesis of the left lobe with the gallbladder being seen anterior and medial to the right lobe. The gastric fundus is displaced medially. **B.** Notice absence of the left hepatic vein, while the middle and right hepatic veins are opacified.

Figure 85-12 Hypoplastic left hepatic lobe. **A.** CT reveals a small amount of liver tissue to the left of the left portal vein, consistent with hypoplasia of the lateral segment of the left lobe. **B.** Topogram shows a transverse, high-riding stomach (arrows) as well as a high-riding transverse colon (TC) due to the underdevelopment of the left lobe of the liver. **C.** Hypoplastic medial segment of the left lobe (arrow).

Each of the cellular components of the liver can give rise to both benign and malignant tumors. Epithelium can degenerate into cystadenomas and cholangiocarcinoma, and mesenchymal tissue may produce hemangiomas or angiosarcomas. In this chapter, the benign primary hepatic neoplasms are discussed (Box 86-1).

Imaging Evaluation of Focal Liver Lesions

The liver is a large and homogeneous organ and therefore is well suited for evaluation by many imaging techniques. The study of liver neoplasms is particularly challenging. In many cases, a

preoperative diagnosis may be achieved with the appropriate combination of imaging techniques in a purely noninvasive fashion. This is important because many adults have benign, nonsurgical hepatic lesions, such as hemangioma or simple cyst. For many tumors, each imaging technique provides a piece of information that, like a puzzle, must be combined with findings from other imaging techniques as well as clinical information for a diagnosis to be achieved.

The study of focal liver lesions by imaging can be likened to a game in which different “players” (imaging techniques) must be used appropriately to achieve the diagnosis.¹ In evaluation of focal liver diseases, the following imaging techniques are available:

- Plain abdominal radiography;
- Nuclear medicine: positron emission tomography (PET), red blood cells (RBCs) tagged with technetium Tc 99m;
- Ultrasonography: gray-scale and color Doppler sonography, contrast-enhanced examinations;
- Multidetector computed tomography (MDCT): nonenhanced scans and contrast-enhanced dynamic scans including arterial, portal venous, and delayed phases;
- Angiography; and
- Magnetic resonance imaging (MRI): nonenhanced, vascular enhanced with gadolinium, reticuloendothelial enhanced with small and ultrasmall superparamagnetic iron oxide particles (SPIOs and USPIOs), hepatocyte enhanced with gadolinium benzyloxypropionictetraacetate (Gd-BOPTA), and gadolinium ethoxybenzyl diethylenetriaminepentaacetic acid (gadoxetate; Gd-EOB-DTPA).

The “plays” that the foregoing players can offer are listed in Box 86-2.

With the widespread use of new cross-sectional imaging techniques such as MDCT and the development of

reticuloendothelial and hepatocyte-specific MRI contrast agents, the role of older techniques such as angiography and nuclear medicine has become more limited. The majority of liver lesions can now be detected and characterized noninvasively, and angiography is required only in exceptional circumstances. Although conventional scintigraphic techniques are only exceptionally used for the evaluation of focal liver lesions, PET and PET/CT are effective techniques, especially for detection of hepatic metastatic disease. Today, most focal liver lesions are diagnosed by ultrasound, CT, and MRI.

As mentioned before, two main groups of liver-specific contrast agents are used in MRI.^{2,3} Superparamagnetic iron oxide particles (SPIOs) are the first group. These particles are taken up by the reticuloendothelial system or Kupffer cells of the liver by phagocytosis.⁴ By causing magnetic field inhomogeneities with shortening of T2 relaxation time, these substances decrease the signal intensity of the normal liver parenchyma on T2-weighted images, which is best seen on T2* or gradient recalled echo sequences for lesion detection. However, to evaluate signal intensity loss for lesion characterization, T2-weighted turbo spin-echo sequences or HASTE (half-Fourier acquisition single-shot turbo spin-echo) sequences are more sensitive. Benign hepatocellular lesions show uptake of these contrast agents, depending on the content of the Kupffer cells.^{4,5} Being an exception for this although lacking Kupffer cells, hemangiomas show a decrease in signal on T2-weighted images because of their relatively large, slow-flowing blood pool that allows the effect of the SPIO particles to occur.^{2,4}

Lesions lacking Kupffer cells, such as malignant lesions or metastases, do not take up SPIO contrast agents, so they appear bright in the dark liver parenchyma on T2-weighted post-SPIO sequences. This increased contrast between the liver and a lesion of nonhepatic origin allows an easy distinction from benign hepatic lesions.⁵

The second group consists of gadolinium-based contrast material, gadobenate dimeglumine (MultiHance; Bracco Diagnostics, Princeton, NJ) and gadoxetate (Primovist; Bayer Schering Pharma, Berlin, Germany). Gadobenate dimeglumine (Gd-BOPTA) and gadoxetate disodium (Gd-EOB-DTPA) are hepatobiliary contrast agents that allow evaluation of the vascularity of the lesion and hepatocellular function within the lesion.³ These contrast agents are taken up by hepatocytes and excreted in the biliary tract.⁶ The administered doses of Gd-BOPTA and Gd-EOB-DTPA are excreted in the bile at a rate of approximately 5% and 50%, respectively (Fig. 86-1). Both act as nonspecific extracellular contrast agents on the early postcontrast phase, whereas they act as hepatocyte-specific agents on the delayed contrast-enhanced phases (40 to 120 minutes for Gd-BOPTA and 10 to 20 minutes for Gd-EOB-DTPA).^{6,7} These contrast agents will be taken up by normal hepatocytes on delayed post-contrast phases.⁸

They increase the signal intensity of the normal liver parenchyma on T1-weighted images. Because malignant lesions do not take up hepatocyte-specific contrast agents during the hepatobiliary phase, they appear hypointense and become more conspicuous.⁹

Hemangioma

PATHOLOGIC FINDINGS

A hemangioma is defined microscopically as a tumor composed of multiple vascular channels lined by a single layer of endothelial cells supported by a thin, fibrous stroma¹⁰ (Fig. 86-2). The

Figure 86-1 Gd-EOB-DTPA elimination: MR image. Gd-EOB-DTPA is eliminated through the biliary system (50%) and kidneys (50%).

Figure 86-2 Hemangioma: pathologic findings. **A.** Microscopic appearance. Note the presence of red blood cells within the vascular channels as well as thin fibrous septa. **B.** Gross appearance. This cut section of liver shows two peripheral hemangiomas. The strikingly vascular nature of this tumor is apparent. **C.** Cut section of a giant hemangioma demonstrates its well-defined borders and inhomogeneous appearance with large fibrotic areas (arrows).

TABLE 86-1 Hemangioma

Pathologic Features	Radiologic Features
Vascular channels	Echogenic mass: ultrasound
Blood-filled cavity	Hyperintense mass: T2-weighted image (MR)
No arteriovenous shunting	Early globular peripheral enhancement on contrast-enhanced helical CT, dynamic Gd-DTPA-enhanced T1-weighted MR and USPIO-enhanced T1-weighted MR

Fibrosis	Hypodense region: CT
	Hypointense region: MR
	Hypoechoic region: ultrasound
Calcification	Dense region: plain films, CT
	Absent signal: MR
	Hyperechoic shadowing region: ultrasound

*See text for full names of imaging agents.

channels are separated by thin fibrous septa, which may form finger-like protrusions into the channels. In gross appearance, it is frequently solitary, well circumscribed, and blood filled and ranges in size from a few millimeters to more than 20 cm.¹⁰ Hemangiomas may be multiple in up to 50% of cases.

Hemangiomas larger than 10 cm are defined as giant hemangiomas. On cut sections, hemangiomas are almost always heterogeneous with areas of fibrosis, necrosis, and cystic change.^{11,12} The radiologic-pathologic correlates of hemangioma are listed in Table 86-1.

INCIDENCE AND CLINICAL PRESENTATION

Hemangioma is the most common benign tumor of the liver, with a reported incidence ranging from 1% to 20%.¹³ The latter figure is the result of a prospective autopsy study in which a dedicated search for this lesion was performed.¹²

Hemangiomas occur primarily in women (female-to-male ratio of 5:1). Although hemangiomas may be present at all ages, they are seen more commonly in postmenopausal women. The worldwide prevalence of this tumor is fairly uniform. In a study of Vilgrain and associates,¹⁴ it was reported that there was a significant association between focal nodular hyperplasia and hemangioma in the liver. Whereas each of these lesions is found commonly as an isolated hepatic mass, in 20% of patients in the study group of Vilgrain and associates, both lesions were present together.

PLAIN RADIOGRAPHIC FINDINGS

Calcification is rare in this tumor; less than 10% of hemangiomas have calcification detectable by plain radiographs.¹⁵ Calcification can be either large and coarse (amorphous calcification within zones of fibrosis) or phlebolith-like thrombi within the vascular channels of hemangioma.

NUCLEAR MEDICINE

Radionuclide scintigraphy for identification of hemangiomas is not performed routinely in all centers, especially outside the United States.¹⁴ With tagged RBC pool scans, there is a defect in the early phases that shows prolonged and persistent “filling

Figure 86-3 Hemangioma: ^{99m}Tc-labeled red blood cell scintiscan. Two-hour delayed scintiscan shows persistent uptake of the isotope within the tumor (arrow).

in” on delayed scans^{16,17} (Fig. 86-3). Many vascular tumors, such as hepatocellular carcinoma, adenoma, and focal nodular hyperplasia, may have persistent uptake, but all exhibit early uptake rather than a defect. Rarely, angiosarcomas can demonstrate the hemangioma pattern of early defect and late isotope uptake.¹⁸ In this context, new hybrid single photon emission computed tomography (SPECT)/CT systems may further aid diagnosis of hemangiomas by means of a more accurate anatomic localization of the lesions. In a study, SPECT/CT increased the accuracy of RBC scintigraphy in classifying the hepatic lesions as hemangiomas and nonhemangiomas from 70.8% to 87.5%.¹⁹

ULTRASOUND

On sonography, hemangiomas are typically hyperechoic and well demarcated and exhibit faint acoustic enhancement^{20,21} (Fig. 86-4). The echogenicity may vary because these tumors may contain cystic and fibrotic regions. Color Doppler ultrasound demonstrates filling vessels in the periphery of the tumor but no significant color Doppler flow deep within the hemangioma itself. Power Doppler, however, may detect minimal flow within hemangiomas, but the pattern is nonspecific and may be seen in hepatocellular carcinomas and metastases.²²

Hemangiomas, like other focal lesions of the liver, are detected and characterized with ultrasound not only by an analysis of echogenicity and vascularity but also by the changes occurring in inflow kinetics of ultrasound contrast agents.²³ In general, ultrasound contrast agents consist of microbubbles of air or perfluorocarbon gas stabilized by a protein, lipid, or polymer shell.²⁴ The small size (approximately the same as RBCs) and stability of the bubbles allow them to traverse the pulmonary and cardiac circulations after intravenous injection.

Figure 86-4 Hemangioma: sonographic findings. **A.** Transverse sonogram demonstrates three small, well-margined, uniformly hyperechoic hemangiomas adjacent to the right hepatic vein. **B.** Larger hemangiomas tend to be inhomogeneous because of hemorrhagic necrosis, scarring, and myxomatous change centrally. **C.** Acoustic enhancement (arrows) is often seen because of the primarily fluid (blood) component of this echogenic lesion. **D** and **E.** Despite the vascular nature of this tumor, the blood flow is very slow, so no significant flow is identified on these color Doppler images.

The bubbles cannot move through the vascular endothelium into the interstitium and remain within the vessel until they disappear by the diffusion of the gas through their thin shell. Therefore, they are true blood pool agents and have a typical half-life of a few minutes in the circulation. Bubbles respond to sound emitted by the imaging transducer by oscillating and returning detectable echoes to the transducer.

On contrast-enhanced ultrasonography, hemangiomas demonstrate a typical specific peripheral nodular contrast enhancement and centripetal fill in. Whereas the “filling in” of the lesion

can take several minutes with CT and iodinated contrast material, the kinetics of ultrasound contrast agents is different, and with them, the process can last even less than a minute.^{23,24} Therefore, imaging in the first 60 seconds is critical in characterizing hemangiomas at ultrasound.

COMPUTED TOMOGRAPHY

Hemangiomas appear as low-density masses with well-defined, lobulated borders on nonenhanced CT scans. Calcification is

observed in 10% to 20% of cases.¹³ After intravenous administration of contrast material, both arterial phase and portal venous phase CT scans show early, peripheral, globular enhancement of the lesion. The attenuation of the peripheral nodules is equal to that of aorta.^{25,26} In a study of Leslie and colleagues,²⁷ the presence of globular enhancement isodense with the aorta was found to be 67% sensitive and 100% specific in differentiating hemangiomas from hepatic metastases. Therefore, if this pattern is visualized, no further evaluation is required. If venous phase CT is obtained, centripetal enhancement that progresses to uniform filling persists on delayed phase images (Fig. 86-5). Although small lesions often fill in completely, large tumors may not show central nonenhancing zones during venous and delayed phases, corresponding to scar tissue or cystic cavities.²⁸ On the other hand, approximately 16% of all hemangiomas and 42% of small ones (<1 cm in diameter) show immediate homogeneous enhancement at arterial phase CT imaging.^{25,29} This feature is relatively challenging for the differential diagnosis because other hypervascular tumors, including hepatocellular carcinoma, also may enhance rapidly during this phase of imaging. In such cases, accurate diagnosis can be made with

delayed phase CT imaging because hemangiomas remain hyperattenuating, whereas hypervascular metastases do not.²⁵ Another important and helpful imaging finding in diagnosis of this type of hemangiomas is that their attenuation is equal to that of the aorta during all phases of dynamic CT imaging.³⁰ Hemangiomas may also be a cause of transient hepatic attenuation differences (THADs).

ANGIOGRAPHY

Although angiography is not routinely used in the diagnostic evaluation of hepatic hemangiomas, knowledge of the characteristic appearances is important because hemangiomas may coexist with metastases. In this scenario, correct identification of the lesions is vital because therapeutic options such as hepatic resection depend on the number and distribution of metastases. On angiography, there is pooling of contrast medium within the hemangioma, producing a characteristic “cotton wool” appearance, without evidence of arteriovenous shunting or tumor neovascularity.³¹ Hemangiomas typically retain contrast medium well beyond the venous phase.

Figure 86-5 Hepatic hemangioma: CT features. **A.** Small hemangiomas (arrow) may demonstrate “flash filling” after intravenous administration of contrast material. The lesion, however, remains isodense with the blood pool, unlike focal nodular hyperplasia, adenoma, hepatoma, and hypervascular metastases, which may also show flash filling. **B** and **C.** Giant hemangioma, which replaces the right lobe, shows peripheral nodular enhancement that progresses in a centripetal fashion. The attenuation of the enhanced portions of the mass is isodense with the blood pool. The central portion of the lesion is a low-attenuation region of central fibrosis. **D.** This hemangioma (H) in the lateral segment of the left lobe is causing a transient hepatic attenuation difference (THAD) in the medial segment of the left hepatic lobe (arrows).

MAGNETIC RESONANCE IMAGING

The study of hemangiomas of the liver is one of the major applications of abdominal MRI (Figs. 86-6 to 86-8). Hemangiomas generally have moderately low signal intensity on T1-weighted images and characteristically demonstrate marked hyperintensity on T2-weighted images, which may contain low-intensity areas correlating with zones of fibrosis.^{11,32-37} They maintain high signal intensity on longer echo time (>120 milliseconds) T2-weighted sequences.³⁸ Nevertheless, the signal characteristics of other masses and neoplasms may overlap with those of hemangioma owing to their similar T2 values, and because of this overlap, characteristics at contrast-enhanced MRI are used for further evaluation.³⁹ Suspected hemangiomas should be evaluated by a dynamic breath-hold sequence, in a manner similar to contrast-enhanced dynamic CT protocol. After intravenous administration of a contrast agent, a fast gradient-echo T1-weighted sequence (20-30 seconds) is repeatedly acquired once per minute until the lesion has filled in completely or nearly completely. In fact, three patterns of enhancement may be seen, depending on the size of the lesion.⁴⁰ The majority of small (<1.5 cm) lesions show uniform early enhancement or peripheral nodular enhancement progressing centripetally to uniform enhancement. This second pattern is commonly seen in medium-sized lesions (1.5-5 cm) and in a few large (>5 cm) lesions.⁴⁰ Most large hemangiomas exhibit peripheral nodular enhancement while the center of the lesion

remains hypointense.⁴⁰ Peripheral nodular enhancement is a useful discriminating feature in the differential diagnosis between hemangiomas and metastases.⁴¹ However, small lesions can be a diagnostic problem because a uniform pattern of enhancement is seen in both hemangiomas and vascular metastases.⁴⁰ Flash-filling hemangiomas may also cause a serious problem regarding their differentiation from hypervascular metastases (e.g., those of malignant neuroendocrine tumors) because of a similar appearance in unenhanced and contrast-enhanced imaging.⁴² In the majority of cases, the combination of T2-weighted images and serial dynamic postgadolinium images allows a confident diagnosis of hemangioma to be made.⁴³ The role of USPIOs has also been evaluated in the characterization of hemangiomas.⁴⁴ This agent is ultimately cleared by the reticuloendothelial system but resides in the intravascular compartment ("blood pool") immediately after injection.⁴⁴ On T1-weighted images, hemangiomas enhance immediately because of their vascularity and become isointense with normal liver. On T2-weighted scans, hemangiomas demonstrate decreased signal intensity and may become isointense to the liver at higher doses of USPIOs.⁴⁴ Hemangiomas do not demonstrate uptake of SPIOs because they do not contain Kupffer cells or normal hepatocytes.¹

Hemangiomas appear isointense or hypointense in the late dynamic phase and hepatocyte phase with use of Gd-EOB-DTPA. The reasons for this are marked hepatocyte uptake of Gd-EOB-DTPA in the surrounding liver, substantially low

Figure 86-6 Hepatic hemangioma: MRI findings. **A.** Nonenhanced T2-weighted MR image shows a large hyperintense hepatic mass. **B.** Nonenhanced T1-weighted image shows low signal intensity. There is a central scar (arrow) that is often seen in large hemangiomas. **C** and **D.** Gadolinium enhancement demonstrates the characteristic peripheral nodular enhancement pattern that shows centripetal progression.

Figure 86-7 Hepatic hemangioma: MRI features. Hemangioma in the posterior aspect of the right hepatic lobe. The lesion is hyperintense on the T2-weighted image (A) and shows gradual peripheral filling on dynamic MRI after intravenous administration of gadolinium (B-E).

overall administered dose of Gd-EOB-DTPA, and substantially short plasma half-life of Gd-EOB-DTPA (Fig. 86-9).⁴²

On diffusion-weighted imaging, hemangiomas show low signal intensity with increased b values and have high apparent diffusion coefficient (ADC) values like simple cysts (Fig. 86-10). However, differentiation between cystic metastases and hemangioma or small flash-filling hemangiomas and hypervascular metastases cannot be achieved solely with this single-pulse sequence, and it should be interpreted in conjunction with contrast-enhanced images.⁴⁵⁻⁴⁷

DIAGNOSTIC WORK-UP

Differentiation of hepatic hemangiomas from other benign and malignant focal liver lesions is one of the most common problems in abdominal imaging.⁴⁸ Most authorities believe that if a

focal liver lesion has the classic appearance of a hemangioma on ultrasound, CT, or MRI examinations, it should be left alone. We believe that in patients with known malignant disease or abnormal liver function test results, one of the tests with high accuracy should be performed, such as multiphasic MDCT or gadolinium-enhanced dynamic MRI, for confirmation. In atypical cases, biopsy should be considered.⁴⁹

Focal Nodular Hyperplasia

PATHOLOGIC FINDINGS

Focal nodular hyperplasia (FNH) is defined microscopically as a tumor-like condition characterized by a central fibrous scar with surrounding nodules of hyperplastic hepatocytes and small bile ductules.¹⁰ The nodules seen in FNH lack normal

Figure 86-8 Hepatic hemangioma: MRI features. **A** and **B.** Sagittal gadolinium-enhanced images show a lesion with a central scar. Although central scars are generally associated with focal nodular hyperplasia, the contrast retention in this lesion establishes the diagnosis of a hemangioma.

central veins and portal tracts. The bile ductules seen in the central scar do not connect to the biliary tree. Vessels course through the tumor and are most abundant in the fibrous scar⁵⁰ (Fig. 86-11A).

In gross appearance, FNH is a well-circumscribed, solitary mass (95%) that is often located on the surface of the liver or pedunculated.¹⁰ On cut section, the majority of these tumors have an obvious central fibrous scar, and although the margin is sharp, there is no capsule (Fig. 86-11B). Hemorrhage and necrosis are rare because this tumor has excellent vascularity. The majority of FNHs are smaller than 5 cm and have a mean diameter of 3 cm at the time of diagnosis. On occasion, FNH replaces an entire lobe of the liver (lobar FNH).¹⁰ The consistency is firm to rubbery, and the color is always paler than that of the surrounding liver. When an FNH is sectioned, it bulges from the cut surface with the stellate scar depressed and forming stellate fibrous septa that course through the tumor. Multiple FNHs have been reported in association with vascular malformations of various organs and neoplasia of the brain.⁵¹ FNH is believed to be a hyperplastic response to an underlying “spider-like” arterial malformation.⁵² It has to be emphasized that on microscopic examination, particularly by needle biopsy, the appearance of FNH resembles that of a cirrhotic process; however, acinar landmarks are not present.⁵³

Radiologic-pathologic correlates of this tumor are listed in Table 86-2.

INCIDENCE AND CLINICAL PRESENTATION

FNH is the second most common benign hepatic tumor, constituting 8% of primary hepatic tumors in autopsy series.¹⁰

FNH is more common in women, predominating in the third to fifth decades of life. Oral contraceptives have a trophic effect on FNH, but there is debate as to whether these agents actually cause this tumor.

Clinically, FNH is usually an incidental finding at autopsy, elective surgery, or cross-sectional imaging. Fewer than one third of cases are discovered because of clinical symptoms, usually right upper quadrant or epigastric pain.

PLAIN RADIOGRAPHIC FINDINGS

Plain radiograph calcification is almost never present. On occasion, a pedunculated FNH lesion may project to the margin of the liver and compress the adjacent stomach or hepatic flexure.⁵⁴

NUCLEAR MEDICINE

In the past, sulfur colloid scintigraphy was the preferred imaging technique in the diagnosis of FNH because of normal tracer uptake in approximately 50%, and a defect is seen in 40% of FNH cases. “Hot spots,” present in 10% of lesions, indicate an increased number of Kupffer cells.⁵⁵ Hepatobiliary scans show tracer uptake in the majority of cases, and isotope excretion can be observed in 50% of delayed scans.⁵⁶ Tagged RBC pool studies show early isotope uptake and late defect. There is no gallium uptake in FNH.

There are only a few studies about PET imaging of FNH. In one study, it was reported that in contrast to liver metastases, there is no increased glucose metabolism in FNH in vivo. Also, the imaging features of FNH on ¹⁸F-fluorodeoxyglucose (FDG) PET imaging are not specific.⁵⁷

Figure 86-9 Hepatic hemangioma: MRI features. A patient with a typical hemangioma in the right lobe of the liver (arrow). The hemangioma is hyperintense on the T2-weighted image (A) and hypointense on the T1-weighted image (B). It shows progressive nodular enhancement on the arterial phase (C) and late phase (D) images. As expected, it does not show any uptake of the hepatobiliary contrast agent and becomes hypointense on the hepatocellular phase image (E).

Today, CT and MRI are used in the diagnostic work-up of FNH. Nuclear medicine studies are reserved for exceptional circumstances.

ULTRASOUND

On gray-scale ultrasound studies, FNH typically appears as a well-demarcated, hypoechoic mass that is homogeneous in tissue texture except for a central scar^{56,58} (Fig. 86-12). Rarely (1.4%), calcifications may be seen within FNH, and the lesion may resemble fibrolamellar hepatocellular carcinoma.⁵⁹ On color Doppler sonography (Fig. 86-13), FNH shows increased

blood flow, and a pattern of blood vessels radiating peripherally from a central feeding artery may be seen, similar to the findings at conventional angiography.⁶⁰ In a contrast-enhanced examination, like hepatocellular carcinoma, FNH in the early arterial phase appears typically as a hyperperfused structure relative to the adjacent liver tissue. However, the specific morphologic features of these two entities are different. FNH typically enhances uniformly without the necrosis and heterogeneity often seen in hepatocellular carcinoma. The stellate lesion vascularity, a central nonenhancing scar, and a tortuous feeding artery are the other typical features of FNH. Nevertheless, portal venous phase imaging is critical for an accurate diagnosis

Figure 86-10 Simple cyst: diffusion-weighted MRI features with different b values. A simple cyst in the right lobe of the liver (arrow). The cyst is markedly hyperintense on the diffusion-weighted image with a b value of 50 (A). With increasing b values (B and C, 400 and 800, respectively), the cyst loses signal intensity. It has a high ADC value (D).

Figure 86-11 Focal nodular hyperplasia: pathology. A. Normal hepatocytes are arranged in incomplete nodules that are partially separated by fibrous tissue (arrow). B. This lesion is usually lighter brown than the adjacent liver. It has a central fibrous scar that consists of fibrovascular tissue, which explains its enhancement pattern after the intravenous administration of contrast medium.

to be reached. During this phase, as opposed to hepatocellular carcinoma, in which washout is generally seen, FNH remains isoechogenic with the portal vein and later with the liver parenchyma.^{23,24}

COMPUTED TOMOGRAPHY

On nonenhanced scans, FNH usually appears as a homogeneous, hypodense mass (Fig. 86-14). In a third of cases, a low-density central area is seen, corresponding to the scar.^{61,62} During the arterial phase of contrast-enhanced CT, FNH enhances rapidly and becomes hyperdense relative to normal liver⁶³ (Fig. 86-15). The low-attenuation scar appears conspicuous against the hyperdense tissue, and foci of enhancement representing arteries may be seen within the scar⁶³ (see Fig. 86-14B). In the portal venous phase and later phases of enhancement, the difference in attenuation between FNH and normal liver decreases and the FNH may become isodense with normal liver.⁶³⁻⁶⁵ Ten-minute delayed images can show increased uptake of contrast material in the scar relative to surrounding liver.²⁶

ANGIOGRAPHY

On angiography, FNH is a hypervascular tumor with a centrifugal blood supply creating a “spoke-wheel” pattern⁶⁶ in 70% of cases. The scar is usually hypovascular. During the capillary phase, an intense and inhomogeneous stain without avascular zones is characteristic. During the venous phase, large veins draining the hypervascular FNH are noted. Angiography is no longer primarily used to diagnose FNH.

MAGNETIC RESONANCE IMAGING

MRI has higher sensitivity (70%) and specificity (98%) for FNH than CT and ultrasound.⁶² On nonenhanced MRI studies, FNH is an isointense tumor on T1-weighted images that becomes slightly hyperintense to isointense on T2-weighted images (Figs. 86-16 and 86-17). The central scar is hypointense on T1-weighted images and hyperintense on T2-weighted images.^{67,68} However, there is overlap in the appearance of FNH and malignant lesions on nonenhanced T1-weighted and

Figure 86-14 Focal nodular hyperplasia: CT features. **A.** On noncontrast scans, FNH is usually isodense with normal liver. Note the central scar. **B.** This lesion shows striking enhancement during the arterial phase with the exception of the scar. **C.** The lesion rapidly becomes isodense with normal liver.

Figure 86-15 Focal nodular hyperplasia: CT findings. Early arterial (**A**) and late arterial (**B**) phase CT scans show FNH as an enhancing lesion (arrows). FNH becomes isodense with the normal liver in the portal venous phase (**C**). (Courtesy Dr. N. Cem Balci, Saint Louis University, Saint Louis, MO.)

Figure 86-16 Focal nodular hyperplasia: MRI features. **A.** A large lesion is seen on this T2-weighted image obtained with fat suppression. The lesion is isointense to the normal liver, and the central scar is hyperintense (arrow). **B.** Gadolinium-enhanced early arterial phase demonstrates homogeneous enhancement of the lesion. The central scar (arrow) does not enhance early.

Figure 86-17 Focal nodular hyperplasia: MRI features. **A.** During the arterial phase of enhancement, the lesion shows robust enhancement with the exception of the central scar (arrow). **B.** The mass rapidly de-enhances, and there is enhancement of the central scar (arrow).

T2-weighted images, and further characterization with contrast-enhanced dynamic studies may be necessary.

FNH, which is a hypervascular tumor, enhances robustly and homogeneously in the arterial phase, with the exception of late-enhancing central scar (see Figs. 86-16 and 86-17).^{38,64,67} Hepatocellular adenomas show less intense enhancement and lack a central scar.

Although other focal liver lesions, such as giant hemangiomas and hepatocellular carcinomas, may also have a central scar, MRI findings can help establish a specific diagnosis. The central scar in giant hemangiomas is typically larger and brighter on T2-weighted images. Because of the presence of scar tissue, calcifications, or necrosis, the central scar in hepatocellular carcinoma tends to show low signal intensity on T2- and T1-weighted images and typically does not enhance that much on contrast-enhanced images. Nevertheless, in some cases, FNH may show atypical features, such as very high signal intensity on T2-weighted images and a central scar with a low signal intensity that causes difficulty in differential diagnosis. In such cases, application of more sophisticated contrast media, such as SPIOs, or hepatobiliary agents, such as Gd-EOB-DTPA, may be necessary to demonstrate the hepatocellular origin of the lesion. On T2-weighted images with SPIO administration, FNH shows loss of signal due to uptake of iron oxide particles by Kupffer cells within the lesion.⁶⁷ The degree of signal loss seen in FNH

with use of SPIOs is significantly greater than in other focal liver lesions, such as metastases and hepatocellular adenoma.⁶⁸

Hepatobiliary agents can also be helpful in characterization of FNH. FNH contains hepatocytes, which take up these agents, resulting in hyperintensity of the lesion relative to the liver on T1-weighted images.⁶⁹⁻⁷¹ On hepatocyte phase images, FNH usually appears isointense or hyperintense relative to the surrounding liver parenchyma and shows the classic popcorn-like enhancement pattern as a result of the accumulation of Gd-EOB-DTPA and poor biliary drainage.^{72,73} Similar to hemangiomas, the central scar appears hyperintense on delayed phase imaging with extracellular agents and hypointense on hepatocyte phase images with Gd-EOB-DTPA.⁴²

Hepatobiliary-specific contrast agents can be useful for differentiation of FNH from adenomas. FNH shows hyperintensity or isointensity except for a central scar in the hepatobiliary-specific phase (typically 20-minute delay for Gd-EOB-DTPA), whereas adenoma usually shows hypointensity (Fig. 86-18).⁷⁴

FNH does not have a true tumor capsule. A pseudocapsule may be present because of compression of the adjacent liver parenchyma and surrounding inflammation. The pseudocapsule is typically a few millimeters thick and hyperintense on T2-weighted images. It may also show some enhancement on delayed postcontrast images.⁶⁴

Figure 86-18 Focal nodular hyperplasia: MRI features. A small FNH in the right lobe of the liver. The lesion is isointense with the liver parenchyma on the T2- and T1-weighted images (**A** and **B**). It shows strong arterial enhancement and becomes visible on the arterial phase image (arrow, **C**). On the portal venous and hepatic venous phase images (**D** and **E**), FNH becomes isointense with the liver. Because it shows uptake of the hepatobiliary contrast agent, it remains isointense with the liver on the hepatocellular phase image (**F**).

Fatty change in the liver parenchyma is not uncommon in patients with FNH. The lesion may tend to show mildly low signal intensity on in-phase gradient-echo T1-weighted images and high signal intensity on out-of-phase images.

As a solid tumor, FNH shows slightly high signal intensity with increasing b values on diffusion-weighted imaging and low signal intensity on ADC mapping, with a reported ADC value between 1 and $1.40 \times 10^{-3} \text{ mm}^2/\text{s}$. However, the ADC values cannot be relied on for lesion characterization because of the overlap with other solid lesions, including adenoma and malignant lesions.^{45,46}

TELANGIECTATIC FOCAL NODULAR HYPERPLASIA

The uncommon telangiectatic subtype of FNH is characterized by the presence of centrally located, multiple dilated blood-filled spaces and is commonly associated with multiple FNH syndrome. In telangiectatic FNH, arteries have hypertrophied muscle media but no intimal proliferation in contrast to the classic form. Furthermore, these abnormal vessels drain directly into the adjacent sinusoids, whereas in classic FNH, connections to the sinusoids are almost never seen.^{47,75} Besides these

histologic differences, there are also reported imaging differences of telangiectatic FNH. Telangiectatic subtype of FNH may be hyperintense on T1-weighted images and strongly hyperintense on T2-weighted images and show persistent lesion enhancement on delayed phase images. All of these features are extremely rare in classic FNH and relatively common in telangiectatic subtype. Furthermore, absence of a central scar is not an uncommon finding in this subentity.⁷⁶

Hepatocellular Adenoma

PATHOLOGIC FINDINGS

Hepatocellular adenoma (HCA) should be considered a spectrum of lesions that are associated with a number of diseases and etiologic factors and that demonstrate a variety of histologic appearances. Accordingly, a new classification of adenomas (Table 86-3) has been proposed in which, in addition to the typical adenoma, anabolic steroid-associated HCA is described separately.¹⁰ This is due to its distinctive histologic appearance, which often resembles that of hepatocellular carcinoma. In addition, multiple hepatocellular adenomatosis should be considered separately from typical HCA.

Typical HCA is defined as a tumor composed of hepatocytes arranged in cords that occasionally form bile¹⁰ (Fig. 86-19). The tumor lacks portal tracts and terminal hepatic veins; consequently, necrosis, hemorrhage, and rupture commonly occur in large tumors.³⁶

In gross appearance, a typical HCA is a large tumor (usually 8-10 cm in diameter at discovery), readily seen from the external surface of the liver.⁴⁰ Pedunculation is seen in approximately 10% of cases. On cut section, its surface is tan and irregular and frequently has large areas of hemorrhage or infarction. However, homogeneous adenomas without rupture can be seen with

numerous blood vessels throughout the tumor and occasionally fibrous septa. Large vessels run through the surface of adenomas.⁴⁰ Most adenomas are solitary.⁵³

On microscopic examination, the tumor is composed of neoplastic cells that are separated by compressed sinusoidal spaces, resulting in a sheetlike pattern.¹⁰ The sinusoids are lined by endothelial cells, and enzymatically active Kupffer cells have been demonstrated in adenomas.⁷⁷ Fatty hepatocytes are frequently present as well. Adenomas rarely undergo malignant transformation to hepatocellular carcinoma, even after years of maintaining a stable appearance.⁷⁸

Radiologic-pathologic correlates of HCA are given in Table 86-4.

INCIDENCE AND CLINICAL PRESENTATION

The majority of HCAs are related to the use of oral contraceptives, with an overall estimated incidence of four adenomas per 100,000 users.^{79,80} Withdrawal of estrogen compounds may result in regression of the HCA, which can require a period of several months.⁸¹

PLAIN RADIOGRAPHIC FINDINGS

When they are sufficiently large, HCAs can cause a right upper quadrant mass on plain radiographs.²³ When these lesions

rupture, free intraperitoneal hemorrhage can occur, producing the typical “ground glass” appearance of free intraperitoneal fluid.

NUCLEAR MEDICINE

As in hemangioma and FNH, nuclear medicine is no longer routinely used in the diagnostic work-up of HCA. There are also no studies reporting usefulness of PET imaging in this context. Sulfur colloid scintigraphy demonstrates a defect in 80% of cases, although tracer uptake can be present in up to 20% of tumors.⁵⁵ Uptake is found in adenomas with a vascular supply sufficient to deliver the isotope to the prominent sinusoids.

Hepatobiliary scans show tracer uptake in the majority of cases; however, no excretion is seen on delayed scans because of lack of bile ductules.⁵⁶ Tagged RBC scintigraphy demonstrates early uptake and a delayed defect, indicating the vascular nature of this tumor.

ULTRASOUND

Sonography typically demonstrates a large hyperechoic lesion with central anechoic areas, corresponding to zones of internal hemorrhage if it is present⁵⁸ (Fig. 86-20). These findings are nonspecific. On occasion, adenomas may undergo massive necrosis and hemorrhage, and the ultrasound appearance is that of a complex mass with large cystic components. Color Doppler ultrasound demonstrates peripheral arteries and veins, correlating well with both gross and angiographic findings. In addition, color Doppler may identify intratumoral veins.⁸² This finding is absent in FNH and may be a useful discriminating feature for HCA.⁸²

On contrast-enhanced ultrasound, adenomas show homogeneous contrast enhancement, typically as a rapid (1-2 seconds) complete centripetal filling in arterial phase. In the early portal venous phase, adenomas become isoechoic or, more rarely, remain slightly hyperechoic relative to liver parenchyma.⁸³ The typical peritumoral arteries with centripetal or diffuse filling of intratumoral enhancement of adenoma in early arterial phase

Figure 86-20 Adenoma: ultrasound findings. There is a large, solid echogenic mass in the right lobe of the liver. Note the fairly well defined hypoechoic rim.

is different from the centrifugal enhancement of FNH.⁸⁴ Hypoechoic nonenhancing areas in the lesion may be seen, possibly representing necrosis or previous hemorrhage. Therefore, in some instances, clear differentiation from FNH cannot be made adequately with the help of the contrast-enhanced ultrasound pattern alone. A correct diagnosis can be achieved only when the spoke-wheel pattern of arterial vessels and a central scar are observed in FNH or intralesional venous signals or nonperfused areas, indicating previous hemorrhage, are present in adenoma.⁸³

COMPUTED TOMOGRAPHY

Nonenhanced CT usually demonstrates a hypodense mass due to the presence of fat and glycogen within the tumor⁵¹ (Fig. 86-21). However, hyperdense areas corresponding to fresh hemorrhage can be noted (Fig. 86-22).

On MDCT, small HCAs enhance rapidly after intravenous administration of contrast medium.⁸⁵ The enhancement does not persist in adenomas because of arteriovenous shunting,¹³ and the lesions become nearly isodense to normal liver on portal venous and delayed scans. A peripheral and centripetal enhancement pattern, reflecting the presence of the large subcapsular feeding vessels, may also be seen.⁷⁸ Larger HCAs may be more heterogeneous than smaller lesions, and the CT appearance is nonspecific.⁸⁵

ANGIOGRAPHY

HCA is manifested angiographically as a hypervascular mass with centripetal flow and large peripheral vessels.^{86,87} Frequently, avascular areas resulting from internal hemorrhage are seen.¹⁵

Figure 86-21 Adenoma: noncontrast CT features. Hyperdense hemorrhage (arrow) is present within the right lobe of the liver.

Figure 86-22 Adenoma: CT features. **A.** Noncontrast scan shows an inhomogeneous mass with areas of low density. **B** and **C.** A mosaic, inhomogeneous enhancement pattern is seen after intravenous administration of contrast material.

MAGNETIC RESONANCE IMAGING

On MRI, adenomas are heterogeneous in appearance (Fig. 86-23). They contain areas of increased signal intensity on T1-weighted images resulting from the presence of fat and hemorrhage and low signal areas corresponding to necrosis⁸⁸ (Fig. 86-24). HCAs are predominantly hyperintense relative to liver on T2-weighted images. As on T1-weighted images, they contain areas of heterogeneous signal intensity reflecting the presence of hemorrhage and necrosis. One third of HCAs have a peripheral rim corresponding to a fibrous capsule.⁸⁹ In most cases, this rim has a low signal intensity on both T1- and T2-weighted images.⁸⁹ Hepatic adenomas typically demonstrate decreased signal intensity on out-of-phase T1-weighted gradient-echo images or fat-suppressed T1-weighted images because of their fat content.³⁸

On contrast-enhanced dynamic studies, the adenomas show early enhancement during the arterial phase and a rapid washout (Fig. 86-25). Hepatic adenomas show a more uniform and moderate enhancement on arterial phase images compared with intense homogeneous and peripheral nodular enhancement patterns of focal nodular hyperplasias and hemangiomas, respectively.

With the use of SPIO contrast agents (ferucarbotran or ferumoxime), adenomas may show an isointense signal intensity relative to healthy liver parenchyma or remain hyperintense on T2-weighted images. A variable number of Kupffer cells within adenomas causes the extent of signal intensity loss with SPIO contrast agents, and iron oxide uptake typically is moderate at best.⁹⁰

After administration of hepatocyte-specific contrast agents, such as gadoxetate (Gd-EOB-DTPA), hepatic adenomas typically appear hypointense relative to normal liver (see Fig.

86-25). Several explanations have been postulated for the signal hypointensity seen in hepatic adenomas in the hepatocellular phase. One explanation holds that hepatic adenomas contain functioning hepatocytes but no bile ductules, and bilirubin and hepatocyte-specific contrast agents therefore cannot be excreted. A more plausible explanation is that the expression of OATP1 or similar membrane transporters is reduced in hepatic adenomas.⁹¹

Although adenomas are uncommon, it is clinically important to differentiate them from FNH because an adenoma may undergo malignant degeneration into hepatocellular carcinoma and have a higher potential for bleeding compared with FNH, possibly resulting in life-threatening hemoperitoneum. Increased hormonal levels during pregnancy or exogenous therapy with estrogen or an anabolic steroid may cause a rapid increase in the size of hepatic adenomas that is associated with an increased risk of rupture. For these reasons, a solitary hepatic adenoma is often resected. However, it may be difficult to recognize a hepatic adenoma at dynamic MRI performed with extracellular gadolinium chelates.⁹²

In hepatocellular phase, the enhancement patterns of adenomas may overlap with those of atypical FNH lesions, including heterogeneous enhancement and rimlike enhancement. It is even reported that adenomas may demonstrate such marked uptake of hepatocyte-specific contrast agents that they appear hyperintense in the hepatocellular phase. The difference in the levels of membrane transporter expression appears likely to be the reason for the disparate appearances of FNH lesions and hepatic adenomas at hepatocellular phase imaging.⁹¹

On diffusion-weighted imaging, as a solid tumor, hepatic adenoma shows slight signal intensity increase with increasing b values and appears hypointense on ADC mapping. The ADC value ranges between 1 and $1.40 \times 10^{-3} \text{ mm}^2/\text{s}$. However, the

Figure 86-23 Adenoma: CT and MRI features. **A.** Nonenhanced CT scan shows a hypodense mass. **B.** On contrast-enhanced CT scan, the lesion shows no enhancement. **C.** On T1-weighted MR image, adenoma is slightly hypointense in comparison with the normal liver, and the fibrous capsule is isointense. **D.** Contrast-enhanced T1-weighted image demonstrates the subcapsular feeding vessels (arrows).

Figure 86-24 Adenoma: MRI features. **A.** In-phase image shows high signal intensity hemorrhage (arrow) within this mass. **B.** Opposed-phase image shows loss of signal intensity of the mass indicating fat. There are multiple areas of focal fatty infiltration (arrows).

ADC values may overlap with FNH and malignant solid lesions like hepatocellular carcinoma.⁹³

MULTIPLE HEPATOCELLULAR ADENOMATOSIS

Multiple hepatocellular adenomatosis is a rare entity characterized by the presence of multiple (more than four) HCAs, usually

present in both hepatic lobes.^{94,95} This entity should not be confused with other hyperplastic hepatocellular conditions, such as nodular regenerative hyperplasia, macroregenerative nodules of cirrhosis, or adenomatous hyperplastic nodules (Table 86-5).

Hepatic adenomatosis can be associated with metabolic disorders such as glycogen storage disease.⁹¹

Figure 86-25 Adenoma: MRI features. A well-demarcated lesion in the right lobe of the liver is slightly hyperintense on the T2-weighted image (A) and slightly hypointense on the T1-weighted image (B). This hepatic adenoma shows strong arterial phase enhancement (C) with washout in the late phase (D). On the hepatocellular phase image (E), adenoma shows no uptake.

TABLE 86-5 Comparison of Hyperplastic Hepatocellular Conditions

Criteria	Focal Nodular Hyperplasia	Hepatocellular Adenoma	Nodular Regenerative Hyperplasia	Multiple Hepatocellular Adenoma	Macroregenerative Nodule
Gross number of lesions	Scar 1 (90%)	Hemorrhage, necrosis 1 (90%)	Bulging nodules Many	Bulging nodules Many	Bulging nodules Many or few
Size (average range)	1-6 cm	4-12 cm	>1.5 cm	2-9 cm	1-6 cm
Key feature	Pseudoductules	Neohepatocytes	Small nodules	Normal cords	Portal tracts
Prior liver disease	None	None	None	None	Submassive hepatic necrosis or cirrhosis
Associated etiology	None	Estrogen, anabolic steroids	Vascular disease	None	None

Modified from Craig GR, Peters RL, Edmonson HA: Tumors of the liver and intrahepatic bile ducts. *Atlas of Tumor Pathology, Second Series*. Washington, DC, Armed Forces Institute of Pathology, 1989.

Nodular Regenerative Hyperplasia

PATHOLOGIC FINDINGS

Nodular regenerative hyperplasia (NRH) is defined as diffuse nodularity of the liver produced by many regenerative nodules that are not associated with fibrosis.⁹⁶ In gross appearance, NRH is characterized by the presence of multiple bulging nodules on the external surface of the liver that on cut surface appear as discrete, round, flat nodules resembling diffuse involvement with metastatic carcinoma (Fig. 86-26A). The nodules vary in size from a few millimeters to several centimeters and are diffusely scattered.

On microscopic examination, the nodules are composed of cells resembling normal hepatocytes, and no fibrosis is noted.⁹⁷ This is an important difference between NRH and regenerative nodules of cirrhosis.

INCIDENCE AND CLINICAL PRESENTATION

NRH is known by numerous synonyms, including nodular transformation of the liver, partial nodular transformation, miliary hepatocellular adenomatosis, adenomatous hyperplasia, diffuse nodular hyperplasia, and noncirrhotic nodulation.¹⁰ NRH is rare, although autopsy series have shown a prevalence as high as 0.6%.⁹⁸ Approximately one third of cases were initially considered cases of FNH. Clinically, NRH is discovered

either incidentally on autopsy or in the work-up of portal hypertension and its complications.

Various systemic diseases and drugs are often associated with NRH⁹⁹⁻¹⁰¹: myeloproliferative syndromes (polycythemia vera, chronic myelogenous leukemia, and myeloid metaplasia), lymphoproliferative syndromes (Hodgkin's and non-Hodgkin's lymphoma, chronic lymphocytic leukemia, and plasma cell dysplasias), chronic vascular disorders (rheumatoid arthritis), Felty's syndrome, polyarteritis nodosa, scleroderma, calcinosis cutis, Raynaud's phenomenon, sclerodactyly and telangiectasia, lupus erythematosus, steroids, and anti-neoplastic medication.⁹⁷

As described earlier, the appearance grossly and therefore at laparotomy is that of a cirrhotic liver with diffuse nodularity.¹⁰²

PLAIN RADIOGRAPHIC FINDINGS

Plain abdominal radiographs may demonstrate splenomegaly, ascites, and other signs of portal hypertension.

NUCLEAR MEDICINE

Because NRH nodules are composed of abnormal hepatocytes with Kupffer cells, they take up ^{99m}Tc-sulfur colloid. The appearance of the liver may be normal if the nodules are small. Large nodules, measuring up to several centimeters, take up sulfur

Figure 86-26 Nodular regenerative hyperplasia. **A.** This rare condition is characterized by small regenerative nodules composed of hepatocytes that compress the surrounding parenchyma and are not surrounded by fibrous tissue. This lack of fibrosis differentiates nodular regenerative hyperplasia from cirrhosis. **B and C.** Multiple robustly enhancing hepatic masses are identified on these contrast-enhanced CT scans in two patients with the Budd-Chiari syndrome. (**A and B** courtesy Michael P. Federle, MD, Palo Alto, CA.)

colloid as well.¹⁰¹ There are no studies reporting the usefulness of PET imaging in this context.

ULTRASOUND

The sonographic appearance of NRH ranges from that of a normal liver to that of a liver with focal nodules that vary in echogenicity. Central hemorrhage within a large nodule may occur and produce a complex mass.

COMPUTED TOMOGRAPHY

On CT scans, the appearance of NRH ranges from that of a normal liver to that of a liver with focal nodules of varying attenuation that are primarily hypodense.¹⁰¹ Central hemorrhage within a large nodule may produce a complex mass with variable density. On contrast-enhanced MDCT scans, arterial phase imaging shows hypervascular lesions (Fig. 86-26B, C) that may become almost imperceptible on portal venous examination.²⁶

ANGIOGRAPHY

On angiography, the typical findings of portal hypertension with esophageal varices, portal collaterals, and splenomegaly are demonstrated.¹⁰¹ On occasion, individual nodules of NRH can be distinguished; they are vascular and fill from the periphery.

MAGNETIC RESONANCE IMAGING

Lesions are isointense to normal liver on T2-weighted images and contain foci of high signal on T1-weighted scans.¹⁰³ These lesions may show robust enhancement after the intravenous administration of Gd-DTPA.

SUMMARY

NRH is an underdiagnosed disease, frequently related to chronic illnesses or prolonged therapy. NRH can be manifested as tiny nodules diffusely involving the liver or as focal larger nodules producing a spectrum of radiologic findings ranging from a normal-appearing liver with associated portal hypertension to multiple hepatic masses.

NRH must be differentiated from other hepatocellular hyperplasias. Currently, hepatocellular hyperplasia is divided into several categories, and some groups overlap with prior concepts of these conditions. FNH, HCA, NRH, multiple HCAs (hepatocellular adenomatosis), and macroregenerative nodules are considered separate entities, and their differences are included in Table 86-5.

Lipomatous Tumors

PATHOLOGIC FINDINGS

Benign hepatic tumors composed of fat cells include lipoma, hibernoma, and combined tumors such as angiomyolipoma (fat and blood vessels), myelolipoma (fat and hematopoietic tissue), and angiomyelolipoma.⁵⁰

In gross appearance, lipomatous tumors are usually solitary, well circumscribed, and round and usually occur in a noncirrhotic liver.¹⁰⁴ The microscopic features are similar to those of lipomatous tumors of soft tissues. There is no sex predilection, and they have been reported in a broad age range (24-70 years).¹⁰ Approximately 10% of patients with tuberous sclerosis and renal angioliipomas have hepatic fatty tumors, either lipoma (Fig. 86-27) or angiomyolipoma (Fig. 86-28).¹⁰⁵ Most lipomatous tumors of the liver are asymptomatic and are incidental findings. These tumors occasionally bleed, causing abdominal pain.

RADIOLOGIC FINDINGS

Angiomyolipomas are highly echogenic on sonography and indistinguishable from hemangiomas.¹⁰⁵ On CT scans, lipomas and angiomyolipomas appear as well-defined masses with attenuation values in the range of those of fat (see Fig. 86-28).^{105,106} On angiography, angiomyolipomas are hypervascular and may show large aneurysms, as in angiomyolipomas of the kidneys.¹⁰⁷ On MRI scans, the fatty component of angiomyolipomas is of high signal on T1- and T2-weighted images.¹⁰⁸ However, hepatocellular carcinomas containing fat deposits may have a similar appearance. The early phase of contrast-enhanced dynamic CT or MRI may be useful in discriminating between angiomyolipomas and hepatocellular carcinomas with fat because the fatty areas of angiomyolipomas are well vascularized and enhance early.¹⁰⁸ Conversely, the areas of fatty

Figure 86-27 Lipoma: CT findings. A hepatic lipoma (arrows) that appears hypodense (fat density) on this contrast-enhanced scan.

Figure 86-28 Angiomyolipoma. **A.** Contrast-enhanced CT scan shows a well-circumscribed, heterogeneous tumor of the right lobe with foci of fat (arrow). **B.** Photograph of the gross specimen shows that the tumor is large and lobulated with areas containing fat (arrow). **C.** Photomicrograph (hematoxylin-eosin stain, original magnification $\times 200$) shows proliferating smooth muscle (arrow), vessels, and adipose tissue (arrowheads). (From Prasad SR, Wang H, Rosas H, et al: Fat-containing lesions of the liver: Radiologic-pathologic correlation. *RadioGraphics* 25:321–331, 2005.)

change in hepatocellular carcinoma are relatively avascular, and enhancement is less obvious.¹⁰⁸ MRI with fat suppression is a useful technique in the characterization of hepatic angiomyolipomas.¹⁰⁹ The lesions have high signal intensity on T1- and T2-weighted images and appear hypointense to liver on images obtained with fat suppression.¹⁰⁹ The presence of large intratumoral vessels (“macroaneurysms”) is a classic feature of large angiomyolipomas. Color Doppler ultrasound, CT, and MRI are useful techniques in the detection of macroaneurysms.¹¹⁰

Other focal fatty lesions of the liver include pseudolipoma and focal fatty change.

PSEUDOLIPOMA

Pseudolipoma is usually due to fat ectopia within Glisson’s capsule. It represents epiploic appendices that become attached to or embedded in the liver parenchyma.¹¹¹

Cysts and Cystic Tumors

The classification of hepatic cysts is somewhat confusing because of varying criteria and incomplete histologic evaluation. Hepatic cysts should be distinguished from other cystic masses of the liver determined by radiologic as well as gross characteristics.¹¹² The following is a discussion of the “true” cyst of the liver, or bile duct cyst, defined by the presence of an epithelial lining.

SIMPLE CYST

Pathologic Findings

A simple hepatic (bile duct) cyst (Fig. 86-29A, B) is defined as a single, unilocular cyst lined by a single layer of cuboidal, bile duct epithelium. The wall is a thin layer of fibrous tissue, and the adjacent liver is normal. In gross appearance, the wall is 1 mm or less in thickness and typically occurs just beneath the surface of the liver, although some may occur deeper. The simple hepatic cyst is considered to be of congenital, developmental origin, although it is usually discovered in the fifth through seventh decades of life.¹¹³

Incidence and Clinical Presentation

Simple hepatic (bile duct) cysts range in incidence from 1% to 14% in autopsy series and appear to occur more commonly in women than in men (5:1).¹⁰ Simple cysts are usually found incidentally, although up to 20% have been reported in surgical series of patients who presented with symptoms caused by a mass effect (abdominal pain, jaundice, intra-abdominal mass).¹¹⁴ Asymptomatic cysts are not usually treated unless they are complicated by hemorrhage or infection. The treatment for symptomatic cysts is wide incision and drainage.

Radiologic Findings

Simple cysts cause a nonspecific photopenic defect on hepatobiliary scans with sulfur colloid and iminodiacetic acid

Figure 86-29 Hepatic cyst. **A** and **B.** Benign unilocular cyst lined by a single layer of cuboidal epithelium. The wall is a thin layer (1 cm) of fibrous tissue, and the adjacent liver is normal. **C.** Transverse sonogram shows an anechoic, well-margined, simple cyst with a thin wall and posterior acoustic enhancement. **D.** Contrast-enhanced CT shows a homogeneous, low-attenuation (8 HU) cyst in the left lobe of the liver. There is no mural enhancement. On MRI, cysts show low signal intensity on the T1-weighted image (**E**) and no enhancement after the intravenous administration of contrast material (**F**).

derivatives. On sonography (Fig. 86-29C), uncomplicated simple (bile duct) cysts are manifested as anechoic masses, with smooth borders, lateral shadowing, posterior echo enhancement, nondetectable walls, no septations, and no mural calcification.

The CT features (Fig. 86-29D) of an uncomplicated hepatic cyst are a well-defined intrahepatic mass; water attenuation; round or oval shape; smooth, thin walls; absence of internal structures; and no enhancement after administration of contrast material.¹¹²

As implied in the definition, simple cysts of the liver are usually solitary but can number fewer than 10. When more than 10 cysts are seen, one of the fibropolycystic diseases should be considered.¹¹⁵

On MRI studies (Fig. 86-29E, F), simple cysts are extremely hyperintense on T2-weighted images and hypointense on T1-weighted images (Fig. 86-30). They usually have a homogeneous, well-defined, oval appearance.³⁸ Cysts with intracystic hemorrhage may show high signal intensity on both T1-weighted and T2-weighted images.¹¹⁶ No enhancement is seen after administration of gadolinium chelates.

Summary

Ultrasound is the best way to confirm the cystic nature of a hepatic mass. Cysts complicated by infection or hemorrhage

may have septations or internal debris as well as enhancement of the wall. Percutaneous aspiration and sclerotherapy with alcohol are useful for treatment of symptomatic hepatic cysts.^{117,118}

BILE DUCT HAMARTOMAS (VON MEYENBERG COMPLEXES)

Bile duct hamartomas (BDHs) are a focal disorderly collection of bile ducts that is due to failure of involution of embryonic bile ducts. With extreme dilation, these ducts become visible on imaging. These lesions are 1 to 5 mm in size (Fig. 86-31). There can be 50,000 to 100,000 BDHs in a normal-sized liver.

Nearly all individuals with adult polycystic liver disease (APLD) have multiple BDHs, and 11% of patients with multiple BDHs have APLD. It is postulated that the larger cysts of APLD result from gradual dilation of the hamartomas. BDHs have a 0.69% to 5.6% incidence at autopsy.

On CT, innumerable cystic lesions less than 5 mm in diameter are present. They show no contrast enhancement. On MRI, BDHs have low signal intensity on T2-weighted images and high signal intensity on T2-weighted images.

Biliary hamartomas do not show uptake of liver-specific contrast agents because of their lack of communication with the bile ducts. On diffusion-weighted imaging, biliary

Figure 86-30 Hepatic cyst: MR features.

A typical simple cyst of the liver. The cyst (arrow) is hyperintense on the T2-weighted image (A) and hypointense on the T1-weighted image (B). It shows no contrast enhancement (C).

Figure 86-31 Multiple bile duct hamartomas (von Meyenberg complexes). A. These are small bile ductules embedded in a fibrous, sometimes hyalinized stroma. Each lumen may contain inspissated bile concretions (arrow), and the lumina may interconnect. These are usually incidental findings at autopsy and cross-sectional imaging. B. They are usually small and multiple, located in the subcapsular region and distributed in both lobes. C. Coronal, T2-weighted MRI scan shows multiple, tiny hyperintense lesions in the liver. D. MRCP images show these hyperintense lesions. They have fluid (bile) signal intensity. E. MRCP image demonstrates innumerable tiny hyperintense cysts typical of this disorder. Arrowheads point to pancreatic duct.

hamartomas, like cystic lesions, show signal intensity loss with increasing b values and appear strongly hyperintense on ADC mapping.⁹

CONGENITAL HEPATIC FIBROSIS AND POLYCYSTIC LIVER DISEASE

Pathologic Findings

Congenital hepatic fibrosis is part of the spectrum of hepatic cystic diseases. Congenital hepatic fibrosis is characterized by aberrant bile duct proliferation and periductal fibrosis.¹⁰ In typical congenital hepatic fibrosis, cysts are not visible without a hand lens. However, in the polycystic liver disease variant, numerous large and small cysts coexist with fibrosis (Fig. 86-32A). In cases of polycystic liver or kidney disease, the liver surrounding the cysts is not normal, frequently containing

von Meyenburg complexes and increased fibrous tissue.¹⁰ In patients with adult polycystic kidney disease, there is hepatic involvement in approximately 30% to 40%.¹¹⁷ On occasion, hepatic cysts occur without radiographically identifiable renal involvement.¹¹⁵

Incidence and Clinical Presentation

The incidence of congenital hepatic fibrosis and polycystic liver disease is difficult to determine because of the various degrees of expression.¹¹⁹ Clinically, the majority of patients present in childhood, when congenital hepatic fibrosis predominates, with bleeding varices and other manifestations of portal hypertension.¹²⁰

In patients with polycystic liver disease predominance, the lesions are usually identified incidentally at radiologic examination. Approximately 70% of patients with polycystic liver disease

also have adult polycystic kidney disease. Congenital hepatic fibrosis is also related to Caroli's disease, which is discussed in Chapter 76.

Radiologic Findings

Cross-sectional imaging shows multiple cysts in the liver (Fig. 86-32B), frequently associated with multiple renal cysts.¹¹⁵ Hypoattenuating cystic lesions demonstrate regular outlines on nonenhanced CT scans and no wall or content enhancement on contrast-enhanced images (Fig. 86-32C). At MRI, cysts show a very low signal intensity on T1-weighted images and do not enhance after administration of gadolinium. Because of their fluid content, on T2-weighted MR images, they show high signal intensity (Fig. 86-32D, E). Signal intensity alterations indicating intracystic hemorrhage are commonly seen.¹¹⁶ Calcification in the cyst wall is occasionally seen, and the cysts may contain blood and fluid levels.¹¹² These hepatic cysts are pathologically identical to simple or bile duct cysts.

CYSTADENOMA

Biliary cystadenoma is a cystic tumor of the liver with a recognized propensity to undergo malignant transformation. It is considered a premalignant lesion and is discussed with cystadenocarcinoma in Chapter 87.

Infantile Hemangioendothelioma

PATHOLOGIC FINDINGS

Infantile hemangioendothelioma (IHE) is a vascular tumor derived from endothelial cells that proliferate and form vascular channels. In gross appearance, IHEs are usually multiple and diffuse; a solitary lesion is an uncommon variant.¹²¹ The nodules of IHEs vary from a few millimeters to 15 cm or more in size. Lesions are usually multiple, nodular, round, red-brown, and spongy to white-yellow with fibrotic predominance in mature cases.¹⁵ Calcification may be present.

On microscopic examination, IHEs are composed of a proliferation of small vascular channels lined by endothelial cells. Cavernous areas as well as zones of hemorrhage, thrombosis, fibrosis, and calcification are common. The cavernous areas noted in some lesions correspond to the areas of puddling of contrast material seen angiographically. The multinodular type may involve other organs and the skin, in which angiomas are also present. The solitary variant has no associated skin hemangiomas.¹⁰

INCIDENCE AND CLINICAL PRESENTATION

IHE is the most common benign vascular tumor of infancy and accounts for 12% of all childhood hepatic tumors.^{122,123} Eighty-five percent of patients with IHE present as young infants between 1 and 6 months of age, with less than 5% of cases detected beyond 1 year of age and females affected more often than males. Clinical findings include hepatomegaly, congestive heart failure (present in up to 25% of cases), thrombocytopenia caused by trapping of platelets by the tumor, and occasional rupture with hemoperitoneum.^{124,125} Most tumors continue to grow during the first year of life and then spontaneously regress, probably because of thrombosis and scar formation.¹²⁶ Cutaneous hemangiomas, as described earlier, are

more commonly present in the multinodular form of IHE, occurring in up to 40% of patients.

PLAIN RADIOGRAPHIC FINDINGS

On plain radiographs of the abdomen, IHE appears as an upper abdominal mass or as hepatomegaly if the liver is diffusely involved. Speckled calcifications may be present.¹²⁷ Chest radiographs may show signs of congestive heart failure in 30% of cases.¹²⁷

ULTRASOUND

Ultrasonographic features of IHE are varied. There is typically a complex liver mass with large draining hepatic veins.¹²⁸ Single or multiple lesions may be seen, and the lesions may range from hypoechoic to hyperechoic. During a period of months, these lesions tend to involute slowly and develop increased echogenicity.^{127,129} Dilated hepatic vasculature with prominent blood flow is typical at Doppler ultrasound if significant arteriovenous shunting is present.

COMPUTED TOMOGRAPHY

On precontrast CT scans, IHE appears as single or multiple hypodense masses with or without calcifications¹³⁰ (Fig. 86-33A). Contrast-enhanced CT shows an enhancement pattern that may resemble an adult giant hemangioma, with "nodular" peripheral early enhancement and delayed progression to the center of the lesion (Fig. 86-33B). In larger tumors, the central portion of the tumor remains hypodense because of fibrosis, hemorrhage, or necrosis.^{126,131}

ANGIOGRAPHY

On angiography, enlarged tortuous feeding arteries as well as draining vessels and large vascular lakes are seen with prolonged pooling of the contrast agent. The aorta typically has a decreased caliber distal to the origin of the hepatic mass, indicating the large blood supply to the tumor.^{132,133}

MAGNETIC RESONANCE IMAGING

On MRI, IHE has a nonspecific appearance and is predominantly hypointense on T1-weighted images and hyperintense on T2-weighted images.¹³⁰ Foci of hyperintense or hypointense signal on T1-weighted scans correspond to areas of hemorrhage and fibrosis.^{130,134} In tumors with arteriovenous shunting and high blood flow, flow voids may be seen on T2-weighted images. On contrast-enhanced dynamic MRI (Fig. 86-33C), the lesions usually demonstrate an enhancement pattern similar to that on MDCT. In some cases, however, the lesion may show a complete "rimlike" enhancement at dynamic imaging, which may simulate other childhood tumors.¹²³

SUMMARY

IHE is the most common liver tumor during the first 6 months of life. These lesions are usually multiple and markedly hypervascular and may be associated with cutaneous angiomas. Although IHE may grow to a large size, producing cardiac failure, it involutes spontaneously with time. The radiologic

Figure 86-33 Infantile hemangioendothelioma: CT and MRI appearance. **A.** On nonenhanced CT, there is a large hypodense lesion in the left lobe of the liver with some peripheral calcification. **B.** After administration of contrast material, there is peripheral enhancement similar to that of a hemangioma identified on the axial MR image. **C.** Coronal MR image demonstrates peripheral enhancement.

findings for IHE are similar to those for multiple hemangiomas of the liver in the adult.

Mesenchymal Hamartoma

PATHOLOGIC FINDINGS

Mesenchymal hamartoma is a benign cystic developmental lesion and is not considered a true neoplasm. It is composed of gelatinous mesenchymal tissue with cyst formation as well as remnants of normal hepatic parenchyma.^{135,136} In gross appearance, mesenchymal hamartoma is a large, soft, predominantly cystic mass measuring 15 cm or more in largest diameter at the time of diagnosis.¹³⁷ These tumors are well defined and encapsulated or pedunculated.¹³⁸ Cysts are present grossly in 80% of cases. On cut section, mesenchymal hamartomas can have either mesenchymal predominance (a solid appearance) or cystic predominance (the bulk of the tumor appears as multiloculated cystic masses). On histologic evaluation, the tumor consists of cysts, remnants of portal triads, hepatocytes, and fluid-filled mesenchyme.

INCIDENCE AND CLINICAL PRESENTATION

Mesenchymal hamartoma is an uncommon lesion, accounting for 8% of all childhood liver tumors.¹³⁷ The majority of cases occur during the first 3 years of life, and there is a slight male predominance.¹³⁶ Clinically, slow, progressive, painless abdominal enlargement is seen. Sometimes rapid enlargement may occur because of rapid accumulation of fluid in the cyst. This enlargement may occasionally cause respiratory distress and edema of the lower extremities.¹³⁹

PLAIN RADIOGRAPHIC FINDINGS

This large tumor is manifested as a noncalcified right upper quadrant soft tissue mass on radiographs.

ULTRASOUND

Sonography demonstrates either large cysts within internal septa (cystic predominance) or, less commonly, smaller cysts with thick septa (mesenchymal predominance).¹³⁸

COMPUTED TOMOGRAPHY

On CT, these tumors appear as well-defined masses with central hypodense areas and internal septa (Fig. 86-34A). Both solid and cystic components may be distinguished.^{138,140} After the administration of contrast media, enhancement of the solid areas may be detectable.¹³¹

ANGIOGRAPHY

Angiography shows a hypovascular or avascular mass causing displacement of vessels. Hypervascularity has been described in the solid portions.^{140,141}

MAGNETIC RESONANCE IMAGING

The MRI appearance of mesenchymal hamartoma depends on whether an individual lesion is predominantly stromal or cystic. For lesions with stromal predominance, the intensity on T1-weighted images is lower than that of the normal liver because of increased fibrosis. Conversely, if there is cystic

Figure 86-34 Mesenchymal hamartoma. CT (A) and MRI (B) appearance. The lesion is markedly cystic and has septa.

predominance, the mesenchymal hamartoma is predominantly hypointense on T1-weighted images and markedly hyperintense on T2-weighted images (Fig. 86-34B). On T2-weighted images, multiple septa can be seen traversing the tumor, indicating that the mass is not a simple cyst.¹³⁴ The stromal components may enhance after the administration of gadolinium-chelate agents.¹⁴²

SUMMARY

Mesenchymal hamartoma is a rare liver tumor that occurs in the first 2 years of life. Hepatoblastoma and IHE have a similar age presentation but are solid, whereas mesenchymal hamartomas are predominantly cystic.

Mesenchymal hamartoma is not a neoplasm but a failure of normal development. Therefore, it does not require extensive surgery; single excision, marsupialization, or incisional drainage may be sufficient therapy.

Mesenchymal hamartoma should not be confused with other cystic-appearing masses that may occur in the liver of toddlers, such as abscesses or hematomas.

Miscellaneous Benign Tumors

BILE DUCT ADENOMA

This benign, solitary, small (<1 cm) mass is composed of small bile ducts and is discovered incidentally at autopsy.¹⁰

LYMPHANGIOMATOSIS

Hepatic lymphangiomas are defined by the presence of multiple masses composed of prominent lymphatic channels that compress the normal hepatic architecture.¹⁰ Usually, it is part of a systemic syndrome in which other organs, including the spleen, skeleton, soft tissues, lung, and brain, are also involved.

LEIOMYOMA

This extremely rare lesion is a well-circumscribed smooth muscle tumor arising in the liver with nonspecific radiologic characteristics.¹⁴³ Several cases of leiomyoma have recently been reported in adults and children infected with human immunodeficiency virus, suggesting that there may be a clinical association between these two entities.¹⁴⁴⁻¹⁴⁶ On ultrasound examination, the lesion may appear solid or hypoechoic with internal echoes.^{145,146} Leiomyomas are of low attenuation relative to the liver on noncontrast CT scans and display two distinct enhancement patterns: peripheral rim enhancement similar to abscesses or homogeneous enhancement resembling hemangioma.¹⁴⁴⁻¹⁴⁶ On MRI, leiomyomas are hypointense relative to the liver on T1-weighted images and hyperintense on T2-weighted images.^{145,146}

FIBROMA (FIBROUS MESOTHELIOMA)

Fibrous mesotheliomas are rare tumors that localize on the surface of the liver.^{53,147} They are usually large and consist histologically of spindle cells and collagen.

ADRENAL REST TUMOR

Adrenal rest tumors are derived from ectopic adrenal tissue that is histologically identical to that in adrenocortical tumors. They are extremely rare.¹⁴⁸

PANCREATIC HETEROTOPIA

Ectopic pancreas in the liver has been rarely described.^{149,150}

INFLAMMATORY PSEUDOTUMOR

Inflammatory pseudotumor is a rare uncommon space-occupying lesion. It is characterized by proliferating

Figure 86-35 Inflammatory pseudotumor. **A.** T1-weighted MR image shows a hypointense lesion in the posterior aspect of the right hepatic lobe (arrow). **B.** The lesion is hyperintense on T2-weighted images. Note the dilated biliary ducts due to cholangitis. **C.** Gadolinium-enhanced arterial phase T1-weighted MR image shows enhancing inflammatory pseudotumor. **D.** On the delayed phase images, the enhancement of the liver parenchyma surrounding the tumor indicates inflammation. (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

fibrovascular tissue mixed with inflammatory cells. The exact etiology of this entity is uncertain, but it has been stated that inflammatory pseudotumors have been associated with lymphoma or inflammatory processes, including inflammatory bowel disease and primary sclerosing cholangitis. Interestingly, they appear to be more common in non-European populations, such as Southeast Asians.¹⁵¹ Inflammatory pseudotumors do not require surgical resection and typically resolve completely.²⁶ On the other hand, it may be challenging to differentiate them from malignant liver neoplasms or abscesses.

Inflammatory pseudotumor is usually large (>3 cm) at presentation. The ultrasound appearance may be hypoechoic, isoechoic, or hyperechoic. On nonenhanced CT images, the

lesion is hypodense or isodense with the liver. At contrast-enhanced dynamic CT imaging, pseudotumors show early arterial enhancement, and they are almost isodense or slightly hyperdense in portal venous phase.²⁶ Delayed phase images may show increased contrast retention within the lesion relative to normal liver parenchyma. The signal intensity on both precontrast T1- and T2-weighted images varies from hypointense to hyperintense. The most common although nonspecific precontrast MRI finding is hyperintensity on T2-weighted images¹⁵² (Fig. 86-35). Contrast enhancement patterns on MRI are similar to those observed on CT. Because of the nonspecific imaging characteristics of this entity, a core biopsy is usually required for accurate diagnosis.¹⁵³

Differential Diagnosis—Incidental Mass

Practical Approach to Liver Masses

Primary malignant neoplasms of the liver are classified by the cell of origin (Box 87-1). Secondary malignant liver tumors are metastases and lymphomas. Overall, metastases are the most frequent malignant tumors of the liver, except in patients with preexisting cirrhosis, in whom primary malignant neoplasms are more frequent.¹

In this chapter, primary malignant liver tumors of hepatocyte origin are discussed first: hepatocellular carcinoma, fibrolamellar carcinoma, and hepatoblastoma. Intrahepatic carcinoma and cystadenocarcinoma that arise from biliary cells are then considered. Angiosarcoma, undifferentiated (embryonal) sarcoma, epithelial hemangioendothelioma, and other mesenchymal sarcomas that originate in the mesenchymal tissue are reviewed. Finally, the secondary liver tumors, lymphomas and metastases, are discussed.

Hepatocellular Carcinoma

PATHOLOGIC FINDINGS

Hepatocellular carcinoma (HCC) is the most common primary hepatic tumor and one of the most common visceral malignant

neoplasms worldwide.² Terms such as *hepatoma* and *primary liver cancer* are often used synonymously with HCC, but they should be avoided in the interest of clarity and the term *hepatocellular carcinoma* should be encouraged.³

HCC is a malignant lesion composed of cells that attempt to differentiate into normal liver, mimicking hepatocyte cords. However, their abnormal growth prevents the malignant hepatocytes from forming normal hepatic acini. Several clinical and histologic patterns occur, and the prognosis differs according to the associated condition (e.g., cirrhosis) and the extent of the tumor at diagnosis.²

In gross appearance, there are three major patterns of growth (Fig. 87-1): single or massive HCC characterized by the presence of a solitary, often large, mass; nodular or multifocal HCC, in which multiple well-separated nodules are seen throughout the liver, mimicking the appearance of metastases; and diffuse or cirrhotomimetic HCC, in which multiple small foci are seen throughout the liver in a diffuse manner.

A gross variant, encapsulated HCC, has a better prognosis because of its greater resectability^{4,5} (Fig. 87-2). Regardless of its gross appearance, HCC is a soft tumor that frequently undergoes necroses and hemorrhages because of lack of stroma.

BOX 87-1 MALIGNANT LIVER TUMORS**HEPATOCELLULAR ORIGIN**

Hepatocellular carcinoma
Atypical hepatocellular carcinoma
Clear cell carcinoma
Giant cell carcinoma
Childhood hepatocellular carcinoma
Carcinosarcoma
Fibrolamellar carcinoma
Hepatoblastoma
Sclerosing hepatic carcinoma

CHOLANGIOCELLULAR ORIGIN

Cholangiocarcinoma
Cystadenocarcinoma

MESENCHYMAL ORIGIN

Angiosarcoma
Epithelioid hemangioendothelioma
Leiomyosarcoma
Fibrosarcoma
Malignant fibrous histiocytoma
Primary lymphoma
Primary hepatic osteosarcoma

Vascular invasion of perihepatic vessels is common.⁶ Conversely, biliary invasion is uncommon.⁶

On microscopic examination, the cells of HCC resemble normal liver cells, and it is often difficult to distinguish normal hepatocytes from cells of HCC or hepatocellular adenoma.⁷ This is of considerable importance in planning an aspiration biopsy of a focal liver lesion. In some cases, the malignant hepatocytes are so well differentiated that they even produce bile, which is seen in tumor cells and in biliary canaliculi. A variety of products can be produced by the abnormal hepatocytes of HCC: Mallory bodies, α -fetoprotein, α_1 -antitrypsin, and other serum proteins. Fat and glycogen are often present in the cytoplasm of HCC hepatocytes. If there are large amounts of fat, the tumor is called clear cell carcinoma of the liver.

The most frequent HCC histologic growth pattern is trabecular, in which the tumor cells attempt to recapitulate the cords seen in normal liver.⁸ The trabeculae are separated by vascular spaces with no stroma or supportive connective tissue. On occasion, the center of the trabeculae contains tumor secretions, giving the tumor a pseudoglandular or acinar pattern. In other cases, the trabeculae grow together, producing a solid pattern (Fig. 87-3).

Figure 87-1 Hepatocellular carcinoma (HCC): gross forms. **A.** Single or massive form. Large mass occupies the right lobe of the liver. **B.** Multifocal or nodular HCC in a cirrhotic liver. Multiple independent tumor nodules are identified. This appearance resembles metastases. **C.** Diffuse or cirrhotomimetic HCC. This cut section shows innumerable nodules of HCC, ranging from several centimeters to subcentimeter in size, replacing the normal liver. In these cases, HCC may be indistinguishable from cirrhosis with macroregenerative nodule on imaging.

Figure 87-2 Encapsulated HCC. **A.** Photomicrograph demonstrates a capsule (arrow) that demarcates the HCC. **B.** Gross specimen demonstrates bands of fibrous tissue (arrow) that surround this HCC.

Figure 87-3 HCC: histologic appearance. **A.** Photomicrograph of a solid or cellular histologic pattern. In solid HCC, the imaging appearance of the tumor is similar to that of normal liver because of its marked cellularity. **B.** Photomicrograph of a well-differentiated HCC with an acinar pattern. Large amounts of tumor secretions are seen within HCC cells (arrow). HCCs with large intratumoral secretions have a lower CT density than normal liver. The spectrum of microscopic findings explains the spectrum of radiologic appearances in HCC.

BOX 87-2 IMAGING TECHNIQUES IN LIVER NEOPLASMS

TO ASSESS VASCULARITY

Contrast-enhanced computed tomography
Gadolinium-enhanced magnetic resonance imaging
Contrast-enhanced ultrasound
Angiography
Blood pool studies (^{99m}Tc -labeled red blood cells)

TO ASSESS HEPATOCYTE FUNCTION OR BILIARY EXCRETION

Magnetic resonance imaging enhanced with hepatocyte-specific contrast agents

TO ASSESS METABOLIC ACTIVITY OF NEOPLASMS

^{18}F -FDG positron emission tomography

TO ASSESS KUPFFER CELL ACTIVITY

Magnetic resonance imaging enhanced with intravenous superparamagnetic iron oxide

TO ASSESS TUMORAL CALCIFICATION

Computed tomography
Ultrasound
Plain radiography

TO ASSESS CAPSULE PRESENCE

Computed tomography (enhanced or unenhanced)
Ultrasound (enhanced or unenhanced)
Magnetic resonance imaging (enhanced or unenhanced)

TO ASSESS INTERNAL NATURE OF NEOPLASMS (e.g., solid versus cystic, hemorrhage, fibrosis)

Computed tomography
Magnetic resonance imaging
Ultrasound

These microscopic variations are important for the radiologist to appreciate because cellular HCCs may appear similar to normal liver, so that only subtle changes in density or echogenicity may be present. However, if there is fat deposition or pseudogland formation, the HCC may appear hyperechoic on ultrasound studies, hypodense on computed tomography (CT) scans, and hyperintense on magnetic resonance imaging (MRI).⁹

The radiologic correlates of the pathology of HCCs are listed in [Box 87-2](#).

An important challenge for radiologists and pathologists lies in the early diagnosis of HCC, particularly within a cirrhotic

liver. Successful treatment of HCCs with any of the available therapies, such as surgical resection, liver transplantation, percutaneous ethanol injection, and transcatheter embolization, is most likely if the lesion is small, so early detection is critical.¹⁰ With this aim, an attempt has been made to standardize the terminology of nodular liver lesions, thereby clarifying the pathogenesis of HCC in the cirrhotic liver and enhancing the early diagnosis of premalignant nodules and small HCCs.¹¹ A cirrhotic nodule is defined as a regenerative nodule composed of hepatocytes and is largely or completely surrounded by fibrous septa. A “dysplastic” nodule, which is an intermediate stage between a cirrhotic nodule and HCC, is at least 1 mm in diameter and contains areas of dysplasia but no histologic evidence of malignancy.^{11,12} Synonyms for dysplastic nodule include adenomatous hyperplasia and macroregenerative nodule.¹¹ Dysplastic nodules are subdivided into low-grade and high-grade types on the basis of findings at light microscopy.¹¹ It is widely accepted that dysplastic nodules are premalignant, although the exact mechanisms of transformation of cirrhotic nodule to dysplastic nodule to HCC have yet to be defined.¹³

INCIDENCE AND CLINICAL PRESENTATION

Although HCC has a similar histologic appearance worldwide, it has a bimodal geographic distribution in terms of incidence and clinical presentation. It is rare in the Western hemisphere (low-incidence areas) and relatively frequent in sub-Saharan Africa and Asia (high-incidence areas).¹⁴

Even in the United States, the incidence varies. According to the World Health Organization, the incidence ranges from 0.9 per 100,000 in women in New York to 30.9 per 100,000 in men of Chinese origin in San Francisco.² Worldwide, the highest incidence is in Japan, where it is reported to be as high as 4.8%.¹⁵

Clinically, in the low-incidence areas, symptoms are insidious in onset and include malaise, fever, and abdominal pain.^{2,6} Jaundice is rare. Liver function test results are normal and indistinguishable from those in cirrhosis, except for elevation of the α -fetoprotein level. Other proteins produced by HCC may give rise to numerous paraneoplastic syndromes, such as erythrocytosis, hypercalcemia, hypoglycemia, hypercholesterolemia, and hirsutism. The usual age at presentation in the low-incidence areas is 70 to 80 years, and the male/female ratio is 2.5:1.^{2,14} Most patients have a long history of alcoholic cirrhosis, hemochromatosis, or steroid use.

In the high-incidence areas, the age at presentation is younger (30-45 years), and men are affected eight times more frequently than women.¹⁴ The primary etiologic factors in high-incidence areas are hepatitis B and C viruses and exposure to aflatoxins. In these areas, HCC is aggressive and may be manifested with hepatic rupture and massive hemoperitoneum.¹⁶

RADIOLOGIC FINDINGS

Plain Radiography

When it is sufficiently large, HCC may appear as a nonspecific upper abdominal mass on plain abdominal radiographs. Calcification is rare in the typical HCC but more common in other hepatocellular neoplasms, such as fibrolamellar carcinoma. In patients with hemochromatosis, plain radiographs of the extremities demonstrate degenerative changes with calcium pyrophosphate deposition disease in cartilages.

Nuclear Medicine

Nuclear medicine is only occasionally used for the detection of HCC. On sulfur colloid studies of Western patients, HCC is manifested as a defect in a cirrhotic liver. Hepatomegaly with heterogeneous uptake of the radionuclide and colloid shift to the spleen and bone marrow are frequently noted.¹⁶ It is reported that 30% to 50% of HCCs are not ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) avid or are only mildly avid^{17,18} because of the abundant amount of the enzyme glucose-6-phosphatase in certain types of HCC. Glucose-6-phosphatase dephosphorylates FDG-6-phosphatase, and as a result of this, FDG “leaks back” into the circulation. However, the use of ¹¹C-acetate as a positron emission tomography (PET) tracer for detection of kinetics and uptake characteristics of fatty acid synthesis in HCC has shown promising results. Well-differentiated HCC, which tends to show negative uptake for FDG because of glucose-6-phosphatase, has uptake of ¹¹C. Unfortunately, ¹¹C has a short half-life of 20 minutes, which leads to the need for an on-site cyclotron. Therefore, in routine situations, there is little role of PET or PET/CT in the diagnosis or staging of HCC.

The soft tissue contrast of liver MRI is far more superior to that of PET for the detection of small primary HCC (<2 cm), especially when liver-specific contrast agents are used. Furthermore, functional MRI techniques, such as diffusion-weighted MRI, have been demonstrated to significantly improve the detection rate of subcentimeter-sized intrahepatic metastasis of HCC compared with conventional MRI alone.¹⁹ If the high sensitivity of liver MRI and the potential of functional MRI can be transferred to combined PET/MRI, it can show a performance no less than that of MRI for the primary diagnosis of HCC. The major advantage of PET/MRI scanners is that MRI evaluation of primary tumor extent and PET evaluation for whole body staging can be performed with a single examination.²⁰

PET/MRI unites the high soft tissue contrast of MRI, the data of functional MRI, and the metabolic information of PET in the evaluation of tumor volume and viability. PET can serve as a tool for differentiating HCCs with low biologic behavior and highly aggressive biologic behavior by measuring tumor ¹⁸F-FDG uptake (standardized uptake value). The aggressiveness of biologic behavior is related to the volume doubling time of HCC and thus is predictive for survival rate, with an inverse relation between the standardized uptake value and survival rate.²¹

Furthermore, ¹⁸F-FDG PET imaging has been proved to be useful for the detection of tumor recurrence in HCC patients after liver transplantation and interventional therapy.²² Although there are studies outlining the high potential of functional MRI techniques, such as dynamic contrast-enhanced MRI and diffusion-weighted MRI, as partners in combination with PET, the exact sensitivity and specificity of PET/MRI for tumor recurrence are still in question.

Ultrasound

The sonographic appearance of HCC is varied (Fig. 87-4). These lesions are frequently hyperechoic, particularly if there is fatty change or marked sinusoidal dilation.²³⁻²⁵ Ultrasonography can detect extremely small tumors and, in combination with serum α -fetoprotein assays, serves as an excellent screening method for high-risk patients with long-standing cirrhosis.^{26,27} This approach to patients has been successful in Asia but has been found to be far less accurate in the United States because of differences in patient body habitus and sonography expertise.

Some authors explain the varied sonographic appearance of HCC on the basis of size. Small HCCs (<3 cm) often appear hypoechoic and are associated with posterior acoustic enhancement; tumors larger than 3 cm more often have a mosaic or mixed pattern.²⁸⁻³⁰ Ultrasound is also capable of demonstrating the capsule in encapsulated HCC, which appears as a thin, hypoechoic band.⁴

Sonography, in conjunction with color and duplex Doppler imaging, can diagnose tumor thrombus in the portal and hepatic veins as well as in the inferior vena cava.^{31,32}

Color Doppler ultrasound has been used to assess the vascularity of HCC.³³ These data plus the resistive index of tumor vessels have been used to differentiate HCC from other tumors.^{34,35} Color Doppler ultrasound demonstrates an intralesional tangle of vessels, the “basket” pattern, in up to 15% of cases, indicating hypervascularity and tumor shunting.^{36,37} Power Doppler has also been assessed in the characterization of HCCs. Although most HCCs show a central pattern of vascularity, so do some hemangiomas and metastases, and the clinical usefulness of this technique is therefore limited.³⁸

The introduction of intravascular contrast agents has improved the ability of ultrasound to diagnose HCC. An HCC typically demonstrates an early hyperperfusion compared with the adjacent normal liver tissue. A chaotic vessel dysmorphism and washout during the portal venous phase are the other characteristics of the tumor.^{39,40}

Computed Tomography

Unenhanced CT scans demonstrate a large, hypodense mass with central areas of lower attenuation that correspond to the tumor necrosis frequently seen in HCC (Figs. 87-5 and 87-6). In North American and European patients, the remainder of the liver shows cirrhosis (60%) or hemochromatosis (20%)^{3,5} (Fig. 87-7).

Multiphasic multidetector computed tomography (MDCT) including nonenhanced, hepatic arterial, portal venous, and delayed phase images is an efficient technique for determination of HCC and preoperative staging of HCC.^{41,42} Because HCC derives most of its blood supply from the hepatic artery, the tumor demonstrates early enhancement during arterial phase and is relatively hypodense on the delayed phase images because of the early washout of contrast medium by arterial blood (see

Figure 87-4 HCC: sonographic features. **A.** The neoplasm is strikingly echogenic in this patient. Because of variable amounts of hemorrhage and necrosis, this tumor can have a variety of sonographic appearances. **B-D.** Dynamic contrast-enhanced sonographic images of the liver of 70-year-old man with segment V hepatocellular carcinoma (diameter, 2.3 cm). Baseline sonographic image (**B**) shows focal hypoechoic hepatocellular carcinoma in right hepatic lobe (cursors delineate margins of the tumor). Arterial phase image after the injection of microbubbles (**C**) shows homogeneous enhancement of the lesion (arrows point to margins of the tumor). Late portal phase image (**D**) obtained at 180 seconds shows that the HCC is clearly hypoechoic with respect to surrounding liver. **E-G.** Hepatocellular carcinoma in 59-year-old man. Unenhanced gray-scale sonogram (**E**) shows peripheral halo sign (arrow). Power Doppler sonogram (**F**) shows heterogeneous vascularity (arrow). Early-phase carbon dioxide-enhanced sonogram (**G**) shows vascularity (arrow) similar to that seen in **F**. (**B-D** from Nicolau V, Vilana R, Catalá V, et al: Importance of evaluating all vascular phases on contrast-enhanced sonography in the differentiation of benign from malignant focal liver lesions. *AJR Am J Roentgenol* 186:158–167, 2006. **E-G** from Chen R-C, Chen W-T, Tu H-Y, et al: Assessment of vascularity in hepatic tumors: Comparison of power Doppler sonography and intraarterial CO₂-enhanced sonography. *AJR Am J Roentgenol* 178:67–73, 2002. Reprinted with permission from the American Journal of Roentgenology.)

Figure 87-5 HCC: CT appearance. **A.** Contrast-enhanced arterial phase CT scan of a patient with multifocal HCC. These lesions demonstrate robust enhancement during the hepatic arterial phase. **B.** On the portal venous phase scan, the lesions become isodense to the relatively normal liver parenchyma. **C.** On delayed phase imaging, lesions become hypodense because of early washout. (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

Figure 87-6 HCC: CT findings. **A.** Early arterial phase (25 seconds) contrast-enhanced CT scan shows a rapidly enhancing lesion in the left lobe of the liver (arrow). **B.** On late arterial phase image (40 seconds), HCC becomes less conspicuous because of early washout (arrow). (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

Figs. 87-5 and 87-6). The tumor has a variable appearance on the portal phase images.⁴³ Small tumors may appear as lesions of different attenuation, whereas larger ones almost always demonstrate central necrosis (see Fig. 87-7). The capsule appears isodense or hypodense relative to the liver during the hepatic arterial phase and enhances on delayed CT images (see Fig. 87-7).

HCC has a tendency to invade the portal and hepatic veins so that an enlarged venous segment that exhibits intraluminal low attenuation is highly suggestive of tumor thrombus. Differential diagnosis of tumor thrombus can be made through demonstration of the expansion of the main portal

vein diameter (≥ 23 mm) and intrathrombus neovascularity on arterial phase images.⁴⁴ Hepatic venous tumor thrombus may extend into the inferior vena cava and even to the right atrium in some cases. CT can also depict complications of HCC, such as hemoperitoneum associated with rupture of HCC and vascular invasion.^{5,45} Ruptured tumors tend to be located in the periphery of the liver and have a protruding contour.⁴⁶ On arterial phase images, a ruptured tumor appears as a nonenhancing hypodense lesion with focal discontinuity and peripheral rim enhancement. This finding is termed the enucleation sign because of its similarity to an enucleated orbital globe with the remaining intact sclera.⁴³

Figure 87-7 HCC: CT features. The heterogeneous appearance on unenhanced (**A**) and contrast-enhanced (**B**) CT scans is suggestive of necrosis. The tumor capsule is visualized as a hypodense rim on **A** and **B** and shows enhancement on delayed phase image (**C**). (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

Figure 87-8 HCC: coronal reformatted CT image. Arterial phase CT image shows the tumor (arrow) and feeding artery (arrowhead) branching from the inferior branch of the left hepatic artery. (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

An additional role for CT lies in the noninvasive evaluation of hepatic arterial anatomy in potential candidates for liver transplantation.⁴⁷ In the majority of cases, three-dimensional (3D) CT arteriography is comparable to conventional arteriography and surgical findings in the delineation of the major hepatic arteries. The technique of 3D CT angiography is safe, convenient, and less invasive than conventional arteriography (Fig. 87-8).⁴⁷

In patients with underlying hemochromatosis, a dense liver resulting from iron deposition is identified on unenhanced CT scans.³

Angiography

On angiography, HCC is a hypervascular tumor with marked neovascularity and arteriovenous shunting. A large hepatic artery, abnormal vessels, and vascular invasion are usually present.⁴⁸ Avascular or hypovascular areas may be present as a result of necrosis or hemorrhage. Extension of the tumor into the porta hepatis and other perihepatic veins is frequently detected.⁴⁹ Hepatic venous tumor thrombus has been described in 6% of cases.⁵⁰ The presence of the “threads and streaks” sign is characteristic of this intravenous tumor thrombus.⁴⁹

Although biliary invasion by HCC is rare, percutaneous or retrograde cholangiography and magnetic resonance cholangiopancreatography (MRCP) may occasionally demonstrate that the tumor is causing obstruction or a mass within the biliary tree.

Magnetic Resonance Imaging

On MRI, HCC has a variable appearance (Figs. 87-9 to 87-11) with low-intensity, isointensity, and high-intensity patterns seen on T1-weighted images, depending on the degree of fatty change, the presence of internal fibrosis, and the dominant histologic pattern.⁵¹⁻⁵³ The capsule of encapsulated HCCs is visualized as a hypointense rim in T1-weighted images.

MRI has also been used to differentiate small HCCs from regenerative nodules of cirrhosis.^{54,55} Cirrhotic nodules are usually of high signal intensity on T1-weighted images.⁵⁶ On T2-weighted images, cirrhotic nodules are isodense or hypointense to the liver.⁵⁶ The relative hypointensity is due to greater accumulation of iron within the nodule than in surrounding liver.⁵⁶ Also, the inflammatory fibrous septa within the liver demonstrate increased signal on T2-weighted images, and consequently cirrhotic nodules appear relatively hypointense.⁵⁶ In contrast, HCCs are often hyperintense on T2-weighted images

Figure 87-9 HCC: MRI contrast enhancement patterns. Hypervascular HCC shows robust contrast enhancement during the hepatic arterial phase (**A**), which rapidly becomes isointense during the portal venous phase (**B**). This tumor rapidly becomes hypointense relative to the normal liver on delayed phase imaging (**C** and **D**). In a different patient with cirrhosis, this small HCC shows uniform enhancement during the hepatic arterial phase (**E**) and washout with ring enhancement on the portal venous phase image (**F**).

Figure 87-10 HCC: the importance of hepatic arterial phase imaging on MRI. The tumor enhances during the hepatic arterial phase (**A**) and becomes isodense with the adjacent parenchyma during the portal venous phase (**B**). Thus this lesion would not be detected if scans were obtained only during the portal venous phase.

Figure 87-11 HCC: MRI appearances.

A. Miliary pattern in which innumerable nodules mimic regenerative nodules of cirrhosis. **B** and **C.** A unifocal tumor that is encapsulated is seen in this patient with cirrhosis. **D** and **E.** This large HCC in the right lobe is inhomogeneous on both pulse sequences.

and can be distinguished from hypointense nodules.⁵⁶ However, some well-differentiated HCCs have signal characteristics similar to cirrhotic nodules, and diagnosis is less straightforward.⁵⁶ HCC arising within a siderotic nodule has a characteristic “nodule within a nodule” appearance on MRI. The HCC appears as a small focus of high signal intensity within the low signal intensity nodule.⁵⁶ These lesions are often demonstrated only at MRI, and MR-guided biopsy is now being performed at many centers.⁵⁷ However, biopsy may be technically difficult because the lesions are small; direct referral for surgery may be a better option if the patient is a good surgical candidate.^{56,57}

As with CT, HCC during dynamic gadolinium-enhanced MRI (Fig. 87-12; see also Fig. 87-9) shows early enhancement in the hepatic arterial phase. In the portal venous phase, the tumor is usually isointense; in delayed phase, it becomes hypointense because of the washout of contrast medium. However, some tumors may show progressive enhancement in the dynamic imaging.⁴³ HCCs larger than 1.5 cm tend to have a fibrous capsule that may be demonstrated as a hypointense band on delayed phase images.⁵⁸ MRI depicts vascular invasion, which is seen in 30% to 50% of patients, as a lack of signal

void on multislice T1-weighted gradient recalled echo and flow-compensated T2-weighted fast spin-echo images.⁵⁹ On gadolinium-enhanced images, the tumor thrombus shows a typical early arterial enhancement.

Intravenous administration of superparamagnetic iron oxide (SPIO) also increases the detection sensitivity of MRI.⁶⁰ MRI with SPIO is especially helpful in the detection of small HCCs in cirrhotic livers. In a study, more HCCs were detected on images acquired with SPIO-enhanced fast low-angle shot and long repetition time sequences (2000/70 and 2000/28) than on unenhanced scans.⁶¹ A potential limitation of this technique is that early HCCs may accumulate iron because of the presence of reticuloendothelial cells and will therefore mimic normal liver parenchyma on SPIO-enhanced sequences.⁶¹ In these cases, unenhanced MR images may provide valuable information concerning the internal morphology of these lesions, enabling the correct diagnosis of HCCs.⁶¹ Hepatobiliary contrast agents such as gadoxetate (Gd-EOB-DTPA) may be useful in the characterization of questionable lesions. Use of hepatobiliary contrast agents may allow differentiation of hepatocellular tumors such as HCC from nonhepatocellular tumors.⁶²

Figure 87-12 HCC (arrows): MRI findings. HCC in the right lobe of the liver that is hyperintense on the T2-weighted image (A) and hypointense on the T1-weighted image (B). It shows arterial enhancement and then washout on the arterial phase (C) and portal venous phase (D) images, respectively.

Preliminary studies suggest that on delayed images with a hepatobiliary contrast agent, well-differentiated HCCs often behave like hepatocytes, appearing isointense or sometimes hyperintense, whereas poorly differentiated HCCs typically do not accumulate the contrast agent and appear relatively hypointense.^{63,64} Although accumulation of contrast material in a lesion does not exclude HCC, if HCC accumulates a hepatobiliary contrast agent, it is postulated to be well differentiated.^{63,64}

Approximately 15 to 20 minutes after the injection Gd-EOB-DTPA, in the hepatocytic phase, hepatocytes take up contrast agent by transporter of organic anion-transporting polypeptides 1B3 (OATP1B3).⁶⁵ Gd-EOB-DTPA works as a T1-shortening agent at the hepatocytic phase, and malignant liver lesions, such as HCC and metastases, are spared from the uptake of contrast material that occurs in the background liver parenchyma.^{66,67}

HCC usually appears hypointense relative to background liver signal intensity in the hepatocellular phase, probably owing to impaired expression of the membrane cotransporters necessary for uptake of the contrast agent. A minority of HCCs appear isointense or hyperintense relative to the background liver signal intensity, demonstrating hepatocellular phase uptake. It is reported that there is a significant correlation between the level of expression of OATP1B3 and the enhancement ratio within the tumors.⁶⁵ On the basis of the data published to date, it appears that HCCs with uniform signal hyperintensity in the hepatocellular phase may be well or moderately differentiated but are rarely if ever poorly differentiated.⁶⁸

Many small hypovascular HCCs can be detected only on hepatocytic phase images, showing no arterial enhancement and only mild washout in the portal venous and equilibrium phases of dynamic MDCT and dynamic MRI with Gd-DTPA (Fig. 87-13).⁶⁹

Gd-EOB-DTPA-enhanced MRI can reveal HCC as a nodule appearing hypointense relative to the background liver parenchyma regardless of its histologic differentiation (Figs. 87-14 and 87-15).^{70,71} Gd-EOB-DTPA-enhanced MRI has higher sensitivity for detection of hypovascular and hypervascular HCCs compared with either dynamic MDCT or dynamic MRI with Gd-DTPA. Gd-EOB-DTPA-enhanced MRI also has higher sensitivity for detection of hypovascular HCC or hypervascular HCC compared with SPIO-enhanced MRI.⁷¹

Regenerative nodules and dysplastic nodules are the two key cirrhotic nodular lesions that are important to identify and differentiate from HCC. Regenerative nodules have primarily portal venous blood supply with mild contribution from hepatic artery blood.⁵⁸ Therefore, they typically do not show early enhancement during the arterial phase of dynamic MRI while enhancing with the rest of the liver in the portal phase. Regenerative nodules are usually isointense on both T1- and T2-weighted images, with the exception of some “siderotic” nodules that contain iron and therefore have a low signal intensity on T1- and T2-weighted MRI.⁵⁸

Dysplastic nodules develop from regenerative nodules and are present in 15% to 25% of cirrhotic livers.⁷² Although they contain atypical hepatocytes, they do not have definite features of malignancy on histology.¹⁰ Depending on the degree of

Figure 87-13 HCC: MRI findings. A patient with liver cirrhosis. T2-weighted (A), T1-weighted (B), arterial (C), and late phase (D) images do not reveal any lesion. On the hepatocellular phase image (E), a tiny HCC is visible in the right lobe of the liver (arrow).

Figure 87-14 HCC: MRI findings. On the T2-weighted image (arrows) (A), there is a suspicious lesion in the left lobe of the liver. This lesion is subtle on the T1-weighted, arterial phase, and late phase images (B-D, respectively). On the hepatocellular phase image (E), the lesion is relatively more suspicious.

differentiation, they are histologically classified as low grade or high grade. Although high-grade ones may develop arterial hypervascularity, dysplastic nodules receive their blood supply mainly from the portal vein.⁷³ High-grade dysplastic nodules are considered premalignant⁷⁴ and can undergo malignant transformation within a short time like 4 months (Fig. 87-16).⁷⁵ Nevertheless, the clinical significance of dysplastic nodules is unclear, and current management guidelines do not advocate aggressive workup of suspected dysplastic nodules.⁷⁶

Their usual MR appearance is that of homogeneous hyperintensity on T1-weighted images and hypointensity on T2-weighted images. A high signal intensity focus within a low signal intensity nodule on T2-weighted images is the nodule within a nodule appearance of a dysplastic nodule with a focus of HCC.^{58,77}

After administration of Gd-EOB-DTPA, in the hepatocyte phase, regenerative nodules generally take up and excrete contrast material because of preserved hepatocellular function and intact organic ion transporters, showing signal intensity similar to liver parenchyma. The number of expressed organic ion transporters decreases with progression of atypia in dysplastic nodules, reducing their ability to take up Gd-EOB-DTPA. Dysplastic nodules that retain their ability to take up but not to excrete the contrast media appear homogeneously or heterogeneously hyperintense because of intracellular cholestasis, whereas nodules that lost their ability to take up contrast media appear hypointense in the hepatocyte phase of Gd-EOB-DTPA.⁷⁸ Such hypointense nodules can be mistaken for HCCs in the hepatocyte phase, and their interpretation is not fully understood.⁷⁸

Figure 87-15 HCC: MRI findings. A patient with a cirrhotic liver. There is a lesion (arrows) in the right liver lobe with some atypical imaging findings for HCC. It is hypointense to isointense on the T2-weighted image (A) and hypointense to isointense on the T1-weighted image (B). On the arterial phase image (C), the lesion shows strong enhancement; nevertheless, it does not show the typical washout on the late phase image (D) despite its big size. On the hepatocellular phase image (E), the lesion does not show any uptake, which is strong evidence for its malignant nature.

Studies have shown that diffusion-weighted imaging can be helpful in differentiating cysts and hemangiomas from solid lesions, but differentiation among different solid lesions such as HCC, focal nodular hyperplasia (FNH), and adenoma may be challenging on the basis of apparent diffusion coefficient (ADC) values alone.^{79,80} A mass in a cirrhotic liver that shows restricted diffusion favors a solid lesion and is more likely to be HCC, especially when other supporting MRI features are present. Conversely, not all HCCs show restricted diffusion on diffusion-weighted imaging. A hepatic mass demonstrating MRI features of hepatoma even with the absence of restricted diffusion can still be HCC. Diffusion-weighted imaging has also been used for monitoring of response to therapies such as transarterial chemoembolization and radioembolization; however, the utility of diffusion-weighted imaging in differentiation of tumor grades is not clearly established.^{81,82}

Fibrolamellar Carcinoma

PATHOLOGIC FINDINGS

Fibrolamellar carcinoma (FLC) is a slow-growing tumor that arises in normal liver. It is composed of neoplastic hepatocytes separated into cords by lamellar fibrous strands.² These lesions have a distinctive microscopic pattern with eosinophilic, malignant hepatocytes containing prominent nuclei⁸³ (Fig. 87-17). Some of the markers usually present in typical HCC, such as inclusions of α -fetoprotein bodies, are not present. The fibrous component accounts for half of the tumor distributed in multilamellate strands, except in larger tumors containing large central scars.²

FLC usually arises in a normal liver, with only 20% of patients having underlying cirrhosis.⁸³ Satellite nodules are often present. The gross appearance of FLC is somewhat similar to that of

Figure 87-16 Multiple dysplastic nodules in the right liver lobe. The largest nodule (arrow) is slightly hyperintense on T1-weighted image (A) and hypointense on T2-weighted image (B). It shows no arterial enhancement (C) or washout (D). On the hepatocellular phase image (E), the lesion shows uptake and remains iso-intense with the rest of the liver parenchyma.

Figure 87-17 Fibrolamellar carcinoma (FLC): pathology. A. Coarse lamellar fibrosis is characteristic of FLC. B. Cut section demonstrates a central scar with radiating septa.

TABLE 87-1
Fibrolamellar Carcinoma

Pathologic Features	Radiologic Features
Lamellar fibrosis (septa), "true scar"	Hypovascular: CT, angiography Hypointense: T2-weighted MRI Calcification: CT, plain radiography, ultrasound
No necrosis or hemorrhage	Homogeneous mass: CT, ultrasound, MRI
No underlying cirrhosis	Normal hepatic morphology except for mass: CT, ultrasound, MRI

FNH in that both tumors have a central scar and multiple fibrous septa. Hemorrhage and necrosis are rare. Radiologic-pathologic correlates are given in Table 87-1.

INCIDENCE AND CLINICAL PRESENTATION

There is some confusion in the literature about the incidence and clinical presentation of FLC because it was not recognized as a biologic entity until the 1980s.⁸⁴ FLC usually occurs in adolescents and adults younger than 40 years and without underlying cirrhosis or other predisposing risk factors.⁸³ There is no sex predominance, and the mean survival is considerably better than that for other types of HCC (45-60 months vs. 6 months), with a high likelihood of cure (40%) if the tumor is surgically resectable.^{85,86}

Clinically, patients with HCC usually present with pain, malaise, and weight loss; jaundice occurs only occasionally, when FLC invades the biliary tree. A palpable mass is seen in two thirds of patients.⁸⁷ α -Fetoprotein levels are usually normal.

RADIOLOGIC FINDINGS

Plain Radiography

On plain abdominal radiographs, FLC frequently appears as a partially calcified upper abdominal mass.

Nuclear Medicine

Nuclear medicine is no longer routinely used in the detection of FLC. Sulfur colloid scintiscans usually demonstrate a defect in a liver that has no evidence of underlying cirrhosis. Multiple defects can be seen in cases of multifocal FLC.

Ultrasound

Sonography typically demonstrates a large, well-defined, lobulated mass (Fig. 87-18) with variable echotexture. FLC usually is of mixed echogenicity (60% of cases) and predominantly contains hyperechoic or isoechoic components.⁸⁸ If the central scar is present, it may be visualized as a central area of hyperechogenicity.

Computed Tomography

On unenhanced CT scans, FLC appears as a hypodense mass with a well-defined contour (Figs. 87-19 and 87-20). Areas of decreased density within the tumor correspond to the central scar or necrosis and hemorrhage.⁸⁹ Stellate calcification within the central scar can also occur.^{87,89} During the arterial and portal phases of dynamic enhanced CT, the "nonscar" portion of FLC enhances heterogeneously. This heterogeneous enhancement

Figure 87-18 FLC: ultrasound findings. The extensive fibrosis present within this neoplasm accounts for the echogenic appearance of this mass.

pattern during the arterial and portal phases probably corresponds to the more vascular, cellular portions of the tumor in comparison with the fibrous (lamellae and scar) and necrotic portions.⁸⁸ On the other hand, the relative delayed phase homogeneity of the tumor probably reflects the washout of the contrast material from its more vascular portions together with delayed enhancement of the fibrous lamellae. In some cases, central scar may also demonstrate delayed enhancement, and the appearance of the tumor, on delayed images, may closely simulate that of FNH. Although FLC is a tumor not characteristically encapsulated, the compressed liver tissue adjacent to it may demonstrate delayed enhancement.⁸⁸ Features that determine the resectability of FLCs, such as portal vein invasion and lymphadenopathy, are well seen on CT scans.⁸⁹⁻⁹¹

Angiography

On angiography, FLC is a hypervascular tumor with compartmentalization in the capillary phase resulting from multiple fibrous septa.⁷⁵ Daughter nodules or secondary lesions may be noted in the capillary phase of arteriography.

Magnetic Resonance Imaging

FLC is hypointense or isointense with normal liver on T1-weighted images and isointense or slightly hyperintense on T2-weighted images.^{92,93} Because of its purely fibrous nature, the scar is hypointense on both T1- and T2-weighted images (Fig. 87-21). However, hyperintensity of the central scar on T2-weighted images has been described in a biopsy-proved FLC that was initially diagnosed as FNH on the basis of imaging findings alone.⁹⁴ The enhancement pattern of FLC seen with gadolinium-enhanced dynamic MRI parallels the enhancement seen with dynamic contrast-enhanced CT. The tumor demonstrates heterogeneous enhancement in the arterial and portal phases and progressively becomes more homogeneous on delayed images (Fig. 87-22).⁹³

On hepatocyte phase images, fibrolamellar HCC appears predominantly hypointense, but components of the tumor may show some uptake of Gd-EOB-DTPA, indicative of a primary liver lesion. FNH, on the other hand, shows intense uptake of hepatocyte-specific (hepatobiliary) contrast agents during the hepatobiliary phase.^{95,96}

Figure 87-19 FLC: imaging features. **A.** CT scan shows an ill-defined low-attenuation area in the left lobe of the liver. **B** and **C.** Enhanced arterial phase CT scans improve definition of the lesion. Note the central low-density area representing necrosis and scar tissue (arrow). **D.** Single photon emission CT (SPECT) image shows the tumor as a large defect (arrows). **E.** Specimen shows the necrotic areas (black arrows), central scar (arrowheads), and intratumoral hemorrhage (white arrows).

Figure 87-20 FLC: CT findings. **A.** This noncontrast scan shows calcification of the central scar. **B.** The central scar is better appreciated on this contrast-enhanced scan.

Figure 87-21 FLC: MRI findings. Unenhanced scan of a low signal intensity mass (A) that showed striking enhancement with the exception of the central scar on the contrast-enhanced image (B).

Figure 87-22 FLC: CT and MRI findings. A patient with a large fibrolamellar carcinoma (arrows). Note the central calcification as depicted on the nonenhanced CT image (A). The lesion is slightly hyperintense on the T2-weighted image (B), with areas of central necrosis. It shows strong enhancement on the arterial and portal venous images (C-D, respectively).

DIFFERENTIAL DIAGNOSIS

The major differential diagnosis with FLC is FNH. FNH can be differentiated from FLC in the majority of cases because the central scar of FNH is hyperintense on T2-weighted images. FNH rarely has calcification within the scar (<1.5% of cases compared with up to 55% of FLC).^{89,97} FNH is usually asymptomatic, whereas patients with FLC usually present with some symptoms. FNH shows strong uptake of hepatobiliary contrast agents. Biopsy demonstrates malignant, eosinophilic hepatocytes in FLC and normal hepatocytes with bile ductules in FNH (Table 87-2).

Hepatoblastoma

PATHOLOGIC FINDINGS

Hepatoblastoma is a malignant tumor of hepatocyte origin that often contains mesenchymal elements.⁹⁸ On microscopic examination, it can be classified as epithelial or mixed (epithelial-mesenchymal).²

Epithelial hepatoblastoma consists of fetal or embryonal malignant hepatocytes. Mixed hepatoblastoma has both an epithelial (hepatocyte) component and a mesenchymal component consisting of primitive mesenchymal tissue and osteoid

material or cartilage⁹⁹ (Fig. 87-23). This histologic classification has prognostic implications; the epithelial type, particularly if it has fetal hepatocyte predominance, has a better prognosis than the other forms. Embryonal epithelial cells are more primitive than fetal epithelial and mesenchymal cells, and tumors with this histologic type have a worse prognosis.^{99,100} A rare anaplastic form of hepatoblastoma has an even poorer prognosis than the mixed form of hepatoblastoma.²

In gross appearance, hepatoblastoma is usually a large, well-circumscribed solitary mass that has a nodular or lobulated surface; 20% are multifocal.² On cut section, the appearance varies according to the histologic type. Epithelial hepatoblastomas are more homogeneous; mixed hepatoblastomas with osteoid and cartilage have large calcifications, fibrotic bands, and overall a more heterogeneous appearance.¹⁰¹

INCIDENCE AND CLINICAL PRESENTATION

Hepatoblastoma is the most common primary liver neoplasm in childhood. It usually develops in the first 3 years of life. Although it may be present at birth or develop in adolescents and young adults,¹⁰² this tumor has a peak incidence between 18 and 24 months of age. Hepatoblastoma is more frequent in males than in females.

Clinically, children with hepatoblastoma present with abdominal swelling that may be accompanied by anorexia or weight loss. More rarely, children may present with precocious puberty due to secretion of gonadotropins or testosterone by the tumor.¹⁰³ The serum α -fetoprotein level is markedly elevated in most patients. This tumor is aggressive, and lung metastases are frequently encountered at the time of diagnosis.¹⁰⁴ Conditions associated with hepatoblastoma include Beckwith-Wiedemann syndrome, hemihypertrophy, familial polyposis coli, and Wilms' tumor.¹⁰³

RADIOLOGIC FINDINGS

Plain Radiography

Because hepatoblastoma is usually a large solitary tumor, a large right upper quadrant mass may be detected on plain abdominal radiographs. Extensive coarse, dense calcification is often present because of osteoid formation.¹⁰⁴

Nuclear Medicine

Hepatoblastoma appears as a large defect on sulfur colloid scans. It may take up gallium and FDG and excrete iminodiacetic acid derivative agents.

Ultrasound

On sonography, hepatoblastoma appears as an echogenic mass that may have shadowing echogenic foci corresponding to intratumor calcification.¹⁰⁴ Hyperechoic or cystic areas, corresponding to hemorrhage within the tumor, or necrotic areas may be present as well.^{105,106} Hepatoblastoma is associated with high Doppler frequency shifts that correlate with the neovascularity typical of this tumor.¹⁰⁷

Computed Tomography

On unenhanced CT scans, hepatoblastoma appears as a solid hypodense mass, with or without calcification, that may occupy large portions of the liver. A lobulated pattern caused by bands of fibrosis can frequently be seen.¹⁰⁴ Calcification and a heterogeneous appearance are particularly extensive in mixed hepatoblastoma. After intravenous administration of a contrast agent, the tumor appears hyperdense, in keeping with its hypervascular nature. In the early arterial phase, enhancement of a thick peripheral rim, corresponding to the viable portion of the tumor, may be seen.¹⁰⁸ Invasion of perihepatic vessels or other structures can be demonstrated.¹⁰⁴ The 3D reconstruction of helical CT data provides important information

TABLE 87-2 Focal Nodular Hyperplasia versus Fibrolamellar Carcinoma		
Features	Focal Nodular Hyperplasia	Fibrolamellar Carcinoma
Hepatobiliary	Shows uptake of contrast agent	No uptake
Scar	Hyperintense on T2-weighted images High signal intensity (flow) on GRE images	Hypointense on T2-weighted images No signal on GRE images
Calcification	No	Frequent
Symptoms	No (usually incidental finding)	Symptomatic
Biopsy	Normal hepatocytes Portal branches Biliary ductules	Malignant eosinophilic hepatocytes No portal branches No biliary ductules

GRE, gradient-recalled echo.

Figure 87-23 Hepatoblastoma: pathologic findings. **A.** Small tumor cells with fairly round to oval nuclei form tubular, acinar, or ribbon-like arrangements. **B.** This tumor typically is a large, solitary mass that is often multinodular because of foci of hemorrhage and necrosis.

in the preoperative assessment of patients with hepatoblastoma¹⁰⁹ (Fig. 87-24). For example, when tumor impinges on the portal vein, the initial treatment is chemotherapy to reduce the size of the lesion. If shrinkage of the tumor away from the vessel is seen on follow-up 3D CT, surgery is indicated.¹⁰⁹

Angiography

On angiography, hepatoblastoma is hypervascular and occasionally has a “spoke-wheel” pattern, reminiscent of FNH, that is due to the presence of multiple fibrous septa and bands. Arteriovenous shunting is uncommon, and invasion of the vessels is rare.¹¹⁰ Hypovascular or avascular zones resulting from hemorrhage can occur within the tumor.

Magnetic Resonance Imaging

Hepatoblastoma is hyperintense on T2-weighted images and hypointense on T1-weighted images. Foci of high signal due to hemorrhage may be seen on T1-weighted images.¹¹¹ On T2-weighted images, internal septa corresponding to fibrosis within the tumor appear as hypointense bands.¹¹² The mixed type may demonstrate a more heterogeneous appearance on T1- and T2-weighted images because of the necrosis, hemorrhage, fibrosis, calcification, cartilage, and fibrous septa contents. After intravenous administration of gadolinium, hepatoblastoma shows immediate diffuse (homogeneous or

heterogeneous) enhancement followed by a rapid washout. On the hepatocellular phase of an MR scan with hepatobiliary contrast agents, the lesion does not show uptake of the agent. MRI also demonstrates the presence of perihepatic vascular invasion. MRI can be more accurate than conventional CT in both assessing preoperative tumor extension and detecting postoperative tumor recurrence.¹¹³ However, CT has an important advantage over MRI in the evaluation of the pediatric abdomen; shorter scanning times result in less motion artifact, obviating the need for sedation.¹⁰⁹

Intrahepatic Cholangiocarcinoma

PATHOLOGIC FINDINGS

Intrahepatic cholangiocarcinoma (ICAC), or adenocarcinoma of biliary duct origin, originates in the small intrahepatic ducts and represents only 10% of all cholangiocarcinomas.² Hilar (Klatskin's) and bile duct cholangiocarcinomas account for the remaining 90%.^{2,114}

In gross appearance, these neoplasms are large, firm masses (Fig. 87-25). On cut section, they are characterized by large amounts of whitish, fibrous tissue. They rarely have internal areas of necrosis and hemorrhage.¹¹⁵

On microscopic examination, the tumor is an adenocarcinoma with a glandular appearance and cells resembling biliary

Figure 87-24 Hepatoblastoma: imaging features. Axial (A), coronal (B), and sagittal (C) CT images demonstrate a large hypodense mass in the right hepatic lobe.

Figure 87-25 Intrahepatic cholangiocarcinoma (ICAC): pathology. **A.** Photomicrograph demonstrates cuboidal cells resembling biliary epithelium with pseudogland formation. **B.** The gross specimen shows a large, whitish, homogeneous lesion within a cirrhotic liver. The tumor extends to the liver capsule. The whitish, homogeneous nature is indicative of the large amount of fibrosis and relative hypovascularity of these neoplasms.

TABLE 87-3 Intrahepatic Cholangiocarcinoma	
Pathologic Features	Radiologic Features
Fibrosis	Calcification: CT, ultrasound Hypodense areas: CT Hypointense areas: MRI Hyperechoic areas: ultrasound
No necrosis or hemorrhage	Homogeneous mass: CT, ultrasound, MRI
Vascular encasement	Hypovascular mass: angiography, contrast CT, MRI Encasement: angiography, Doppler ultrasound, contrast CT, MRI

epithelium.¹¹⁶ Mucin and calcification can often be demonstrated. A large amount of desmoplastic reaction is typical of cholangiocarcinoma.

Pathologic-radiologic correlates of this lesion are given in Table 87-3.

INCIDENCE AND CLINICAL PRESENTATION

ICAC is the second most common primary hepatic malignant neoplasm in adults. It is usually seen in the seventh decade of life, and there is a slight male predominance.²

Clinical signs and symptoms are related to the site of origin of the tumor. Symptoms are vague until the tumor is far advanced, and patients present with abdominal pain and a palpable mass in the upper abdomen. Jaundice is rarely a presenting symptom in ICAC, whereas it is common with hilar or ductal cholangiocarcinoma.

RADIOLOGIC FINDINGS

Plain Radiography

On plain radiographs, ICAC may appear as a large upper abdominal mass. Calcification is frequently seen and results from mucous secretions or amorphous calcification in sclerotic areas.¹¹⁵

Nuclear Medicine

Sulfur colloid and hepatobiliary scans demonstrate a large defect; signs of cirrhosis are present in 20% of patients with ICAC.¹¹⁵ There is no accumulation of gallium in ICAC. Red

blood cell scans demonstrate a defect without late filling, reflecting the markedly hypovascular nature of this tumor.

Ultrasound

On sonograms, ICAC appears as a homogeneous mass that is usually hypoechoic.¹¹⁷ Satellite nodules may be seen. Calcified foci can be seen as high-level echoes with acoustic shadowing. Although the majority of the tumors appear slightly hyperperfused in color Doppler ultrasound studies, Doppler imaging findings vary widely.³⁶ In the arterial phase of contrast-enhanced sonography, the perfusion picture of ICAC is variable but mainly hyperperfused. In the late portal venous phase, the tumor is contrasted as punched-out defects.

Computed Tomography

On unenhanced CT, this lesion usually is manifested as a homogeneous, hypodense mass. After injection of contrast material, there is early peripheral enhancement with delayed, persistent central enhancement that may take 5 to 15 minutes to be manifested¹¹⁵⁻¹²⁰ (Fig. 87-26). Retraction of the overlying liver capsule is a feature suggestive of ICAC.¹¹⁷ A central scar may be seen in 30% of cases.¹¹³ Small areas of necrosis, hemorrhage, mucin, and calcification can also be present within the tumor. Biliary dilation adjacent to the tumor is another finding seen in 20% of the cases.

Extension through the hepatic capsule and invasion of organs adjacent to the liver are common in ICAC but rare in HCC. Invasion of vascular structures around the liver is uncommon but may be seen with ICAC.

Angiography

On angiography, ICAC is predominantly hypovascular with small, thin vessels corresponding to the fibrous nature of this tumor.¹²¹ Encasement of hepatic arteries and other major vessels is associated with the degree of sclerosis resulting from the tumor.

Magnetic Resonance Imaging

On MRI, ICAC appears as a large mass of decreased signal intensity on T1-weighted images and increased signal on T2-weighted images.^{122,123} A central area of hypointensity is seen in some cases on T2-weighted images and corresponds to the central scar. The pattern of enhancement on Gd-DTPA-enhanced scans depends on the size of the lesion (Fig. 87-27).¹²³

Figure 87-26 ICAC: CT features. **A.** This lesion does not enhance on the portal venous phase image. **B.** Significant contrast enhancement, with the exception of the central scar, is present on the 10-minute delayed scan.

Figure 87-27 ICAC: MRI findings. A patient with situs inversus (arrows). The lesion is in the "left" liver lobe and is an ICAC. It is poorly demarcated and hyperintense on the T2-weighted image (**A**). ICAC is hypointense on the T1-weighted image (**B**) and shows late enhancement as depicted on the arterial (**C**) and late phase (**D**) images.

Larger ICACs (>4 cm) show peripheral enhancement that progresses centripetally and spares the central scar (Fig. 87-28). Smaller lesions (2-4 cm) enhance homogeneously.¹²³ These patterns of enhancement may also be seen in hemangiomas. However, the degree of enhancement of hemangiomas is greater.^{122,123} In addition, ICACs may have other features, such as satellite nodules, invasion of the portal vein, and dilation of intrahepatic bile ducts distal to the lesion, that are not associated with hemangiomas.¹²² ICACs do not show uptake of hepatobiliary contrast agents during the hepatocellular phase scans. On diffusion-weighted imaging with increasing b values, ICACs show high signal intensity and low ADC values, indicating their malignant character.

Cystadenoma and Cystadenocarcinoma

PATHOLOGIC FINDINGS

Biliary cystadenoma and cystadenocarcinoma are currently considered forms of the same disease, with cystadenocarcinoma being overtly malignant and cystadenoma having malignant potential. Transformation of cystadenoma to cystadenocarcinoma is a recognized complication.^{124,125}

On microscopic examination (Fig. 87-29), cystadenomas and cystadenocarcinomas are commonly mucinous, but a serous variety is also recognized. The locules of these tumors

Figure 87-28 ICAC: MRI findings. No significant enhancement of the tumor is noted on the early phase scan (**A**), but on the 10-minute delayed scan (**B**), there is enhancement with the exception of the central scar. In a different patient, the lesion in the caudate lobe does not enhance on early scan (**C**) but does on delayed scan (**D**).

Figure 87-29 Biliary cystadenoma: pathology. **A.** Photomicrograph shows the cyst wall lined by benign cuboidal epithelium (arrow) with a subepithelial mesenchymal "ovarian-like" stroma. **B.** The cut resected left lobe shows the fibrous wall of the tumor, multiple tumor nodules (curved arrow), and loculi. The mass arises from the compressed bile duct (straight arrow). (From Levy AD, Murakata LA, Abbott RM, Rohrmann CA Jr: Benign tumors and tumorlike lesions of the gallbladder and extrahepatic bile ducts: Radiologic-pathologic correlation. *RadioGraphics* 22:387–413, 2002.)

are lined by columnar, cuboidal, or even flattened epithelium.² Polypoid projections and papillary areas are frequently present. There is a well-formed wall, and focal calcification within the wall is rare. Biliary-type epithelium lines the cysts. In cystadenocarcinoma, malignant epithelial cells line the cysts. Pathologists have categorized biliary cystadenocarcinoma by whether ovarian stroma is present or absent.¹²⁶ Cystadenocarcinoma with ovarian stroma is found in women and has an indolent course and a good prognosis, whereas tumors without ovarian stroma are found in both sexes and have an aggressive clinical course and a poor prognosis.¹²⁶

In gross appearance, these tumors are usually solitary and may become up to 30 cm in size.² The surface is shiny, smooth, or bosselated. On cut section, multiple communicating locules of variable size have a smooth and glistening lining. Papillary excrescences or mural nodules are seen in the tumor wall.

INCIDENCE AND CLINICAL PRESENTATION

Cystadenomas and cystadenocarcinomas are rare and represent only 5% of all intrahepatic cysts of bile duct origin.¹²⁷ They are probably congenital in origin because of the presence of

aberrant bile ducts. There are no associated pathogenic factors, and these tumors usually occur in middle-aged women.²

A “microcystic” cystadenoma variant is composed of multiple small cysts lined by a single layer of cuboidal epithelial cells that are rich in glycogen.¹²⁸ The papillary features and the cellular mesenchymal stroma typical of the mucinous variety of cystadenoma or cystadenocarcinoma are not seen in microcystic, glycogen-rich cystadenoma. No radiologic descriptions of microcystic cystadenoma of the liver have been published.

RADIOLOGIC FINDINGS

Endoscopic retrograde cholangiopancreatography (ERCP) can show communication of the tumor with the bile duct (Fig. 87-30). Cystadenoma or cystadenocarcinoma of the liver usually appears as a large, unilocular or multilocular mass on cross-sectional imaging. Ultrasound nicely demonstrates the septa as well as the mural nodules in the wall of these tumors (Fig. 87-31). Good correlation is seen between the nodularity and septation on ultrasound scans and gross specimens.¹²⁶

On CT scans, these tumors are large, unilocular or multilocular low-attenuation intrahepatic masses¹²⁶ with well-defined thick fibrous capsules, mural nodules, and internal septa¹²⁹ (Fig. 87-32). Calcification may be seen within the wall and septa in a minority of cases.¹²⁶

Figure 87-30 Biliary cystadenoma: ERCP. Lateral radiograph of the abdomen obtained after ERCP shows communication of the tumor (arrow) with the biliary system. The gallbladder has an anterior location. (From Levy AD, Murakata LA, Abbott RM, Rohrmann CA Jr: Benign tumors and tumorlike lesions of the gallbladder and extrahepatic bile ducts: Radiologic-pathologic correlation. *RadioGraphics* 22:387–413, 2002.)

Figure 87-31 Biliary cystadenoma: sonographic findings. **A.** Transverse image of the liver shows a well-defined anechoic cystic structure with enhanced through-transmission. There are multiple echogenic tumor excrescences extending into the cyst lumen (arrows). **B.** Transverse image of the left hepatic lobe in a different patient reveals a complex anechoic cyst containing echogenic septa (straight arrow) and tumor nodules (curved arrow). **C.** Transverse image of the liver in a different patient shows a biliary cystadenoma composed of complex fluid containing diffuse low-level internal echoes. Echogenic septa course through the complex fluid. A portion of the tumor (asterisk) contains simple anechoic fluid. (From Levy AD, Murakata LA, Abbott RM, Rohrmann CA Jr: Benign tumors and tumorlike lesions of the gallbladder and extrahepatic bile ducts: Radiologic-pathologic correlation. *RadioGraphics* 22:387–413, 2002.)

On angiography, most cystadenomas and cystadenocarcinomas are avascular, although a small peripheral vascular blush may be seen in a few cases.¹²⁶

On MRI, the tumors are multiseptate and have predominantly high signal on T2-weighted images and mixed or low signal on T1-weighted images (Fig. 87-33). The areas of high signal on T1-weighted images represent hemorrhagic fluid components.¹²⁶ A low signal rim on T2-weighted images may be due to hemorrhage in the wall of the lesion.¹²⁶ Variable signal intensity within the locules of biliary cystadenoma and cystadenocarcinoma on both T1- and T2-weighted images was reported as a new sign.¹³⁰ This feature may prove extremely useful in the characterization of a multiseptate hepatic lesion as cystadenoma or cystadenocarcinoma.

Figure 87-32 Biliary cystadenoma: CT. Contrast-enhanced scan shows a multilocular cyst with septations and mural calcifications (straight arrow) in the left hepatic lobe. There is duct dilation and extension of the cyst into the left hepatic and common bile ducts (curved arrow). (From Levy AD, Murakata LA, Abbott RM, Rohrmann CA Jr: Benign tumors and tumorlike lesions of the gallbladder and extrahepatic bile ducts: Radiologic-pathologic correlation. *RadioGraphics* 22:387–413, 2002.)

It is impossible to distinguish cystadenomas from cystadenocarcinomas radiologically. However, the combination of septation and nodularity is suggestive of cystadenocarcinoma (Fig. 87-34), whereas septation without nodularity is seen only in cystadenoma.¹²⁶ In addition, the presence of distant metastases, adenopathy, or other signs of widespread malignancy are consistent with cystadenocarcinoma.¹²⁶ It is also difficult to distinguish between cystadenoma or cystadenocarcinoma, hydatid disease, and abscess on cross-sectional imaging.^{126,131} However, use of clinical and laboratory findings should enable identification of an infectious cause.¹²⁶

Angiosarcoma

PATHOLOGIC FINDINGS

Angiosarcoma of the liver is a malignant tumor derived from endothelial lining cells that occurs primarily in adults with exposure to a variety of chemical agents and radiation (thorium oxide administration).^{2,132,133}

On microscopic examination, angiosarcomas are composed of malignant endothelial cells lining vascular channels of variable size from cavernous to capillary. These vascular channels try to form sinusoids. Thorotrast particles can be found within the malignant endothelial cells in cases of Thorotrast-induced angiosarcoma.

In gross appearance, the majority of angiosarcomas are multiple and have areas of internal hemorrhage.¹³² When angiosarcoma appears as a single, large mass, it does not have a capsule and frequently contains large cystic areas filled with bloody debris.

The radiologic correlates of the pathology of angiosarcoma are given in Table 87-4.

INCIDENCE AND CLINICAL PRESENTATION

Angiosarcoma is a rare neoplasm that occurs most frequently in men (2:1 to 4:1 more often than in women) in the seventh decade of life. It is 30 times less common than HCC.¹³⁴ Angiosarcoma is associated with previous exposure to toxins such as Thorotrast, vinyl chloride, arsenicals, and steroids. It has also been found in association with hemochromatosis.

Figure 87-33 Biliary cystadenoma on MRI. A. Fast spin-echo T2-weighted MR image shows a multilocular, septated mass (arrows) in segment VII of the liver, with high signal intensity within the tumor. **B.** Corresponding portal venous phase gadolinium-enhanced T1-weighted image shows enhancement of the capsule and septa. (From Mortelet KJ, Ros PR: Cystic focal liver lesions in the adult: Differential CT and MR imaging features. *RadioGraphics* 21:895–910, 2001.)

Figure 87-34 Biliary cystadenocarcinoma: imaging features. **A.** MRCP. Biliary cystadenocarcinoma in a 65-year-old woman with abdominal pain. Single-shot fast spin-echo MRCP image shows a large, fluid-filled mass in the left hepatic lobe (solid arrows), with proximal dilation of the left intrahepatic bile ducts. The low signal intensity filling defects in the mass are related to polypoid masses of the wall, and the low signal intensity filling defect in the common hepatic duct (open arrow) is related to mucin secreted by the mass. In a different patient, arterial (**B**) and equilibrium phase (**C**) CT scans show a large, bilobular, cystic mass with internal septation and calcification (arrows) that involves the left hepatic lobe. Papillary excrescences and mural nodules along the cyst wall enhance well during the arterial phase. (**A** from Vitellas KM, Keogan MT, Spritzer CE, et al: MR cholangiopancreatography of bile and pancreatic duct abnormalities with emphasis on the single-shot fast spin-echo technique. *RadioGraphics* 20:939–957, 2000. **B** and **C** from Lee WJ, Lim HK, Jangy KM, et al: Radiologic spectrum of cholangiocarcinoma: Emphasis on unusual manifestations and differential diagnoses. *RadioGraphics* 21:S97–S116, 2001.)

TABLE 87-4
Angiosarcoma

Pathologic Features	Radiologic Features
Multiple nodules	Hyperechoic nodules: ultrasound Hypodense nodule (central): CT Hypointense nodule: MRI
Thorium oxide (Thorotrast) deposition	Metallic density: CT
Areas of hemorrhage	Heterogeneous mass: CT, ultrasound Hyperdense regions: CT Hyperechoic regions: ultrasound Hyperintense regions: T1-weighted MRI
Vascular channels	Persistence of contrast medium: red blood cell scintigraphy, contrast-enhanced CT and MRI

Clinically, patients with angiosarcoma frequently present with generalized weakness, weight loss, abdominal pain, hepatomegaly, and ascites. Thrombocytopenia caused by platelet sequestration within a large angiosarcoma may be present. Rupture and acute hemoperitoneum are rare.^{135,136}

RADIOLOGIC FINDINGS

Plain Radiography

The plain abdominal radiographic findings depend on the presence or absence of prior Thorotrast exposure. If there is no history of Thorotrast exposure, the findings of angiosarcoma are nonspecific. A soft tissue density mass in the upper abdomen may be detected if there is a large predominant angiosarcoma nodule.

If there is a history of Thorotrast exposure, localized areas of increased density, in a network fashion, are visualized in the liver and spleen as well as in the mesenteric and celiac lymph nodes. Circumferential displacement of the Thorotrast by nodules of angiosarcoma can be identified on plain films.¹³⁷

Nuclear Medicine

Sulfur colloid scans demonstrate either solitary or multiple filling defects in an often diffusely abnormal liver. A defect is also noted on hepatobiliary and gallium scans. Tagged red blood cell pool studies may show early as well as late uptake. Angiosarcoma, therefore, can mimic the appearance of hemangiomas on red blood cell studies, with persistent uptake of the tracer.¹³⁸

The retention of the tagged red blood cells by this tumor is not as prolonged as that by hemangiomas, however.

Ultrasound

On ultrasound studies, angiosarcomas appear as either single or multiple hyperechoic masses. The echo architecture is heterogeneous because of hemorrhage of various ages.

Computed Tomography

CT scans show the reticular pattern of deposition of Thorotrast extremely well in both the liver and the spleen. Circumferential displacement of Thorotrast in the periphery of a nodule has been described as a characteristic finding of angiosarcoma.¹³⁸

When there is no evidence of Thorotrast deposition, angiosarcomas are manifested with single or multiple masses that are hypodense on unenhanced CT scans except for hyperdense areas of fresh hemorrhage. In case of rupture of the hepatic angiosarcoma, the diagnosis is made by demonstrating free intraperitoneal fluid and focal high-density area adjacent to the tumor representing acute blood clot.¹³⁹ Centripetal enhancement with contrast material can be seen mimicking the hemangioma pattern.¹⁴⁰ However, in most cases, angiosarcomas have additional imaging features that are atypical for hemangiomas, such as focal areas of enhancement that show less attenuation than the aorta or peripheral ring-shaped enhancement.

Angiography

On angiography, these moderately hypervascular tumors show diffuse puddling of contrast medium that persists into the venous phase.¹⁴¹ Angiosarcomas are fed by large peripheral vessels, and centripetal flow can be recorded angiographically. Avascular areas corresponding to central hemorrhage can be seen within the tumors. On occasion, angiosarcomas may rupture, and angiography and CT can demonstrate the bleeding as well as the presence of hemoperitoneum.¹³⁶

Magnetic Resonance Imaging

Angiosarcoma (Fig. 87-35) is of low signal intensity on T1-weighted images and of predominantly high signal on T2-weighted images with central areas of low signal.^{121,142} Imaging features that have been described on T2-weighted

images include fluid-fluid levels reflecting the hemorrhagic nature of the tumor and marked heterogeneity with focal areas of high intensity along with septum-like or rounded areas of low intensity. On T1-weighted imaging, areas of hyperintensity are related to hemorrhage. During dynamic scanning after intravenous administration of Gd-DTPA, peripheral nodular enhancement is seen, which progresses centripetally.¹⁴² On delayed postcontrast images, the peripheral enhancement persists while the center of the lesion remains unenhanced and may represent fibrous tissue or deoxyhemoglobin.^{121,142} Although the pattern of enhancement mimics hemangiomas, the inhomogeneity of angiosarcomas on T2-weighted images is not seen in hemangiomas.^{121,142} Because Thorotrast does not produce a recognizable MR signal, it, like the presence of calcification, may easily be missed.

Undifferentiated (Embryonal) Sarcoma

PATHOLOGIC FINDINGS

Undifferentiated (embryonal) sarcoma (UES), or mesenchymal sarcoma, is a malignant tumor occurring primarily in children. It is composed of primitive, undifferentiated spindle cells, with frequent mitoses and myxoid stroma, that resemble primitive (embryonal) cells.¹⁴³ In gross appearance, UES is a large, usually solitary, spherical mass with well-defined margins (Fig. 87-36). On occasion, a pseudocapsule is present. On cut surface, it has a variegated, glistening appearance with cystic areas of variable size that contain necrotic debris, hemorrhagic fluid, blood, or gelatinous material.^{143,144} Cystic tumors are seen more frequently than solid ones.

INCIDENCE AND CLINICAL PRESENTATION

UES is the fourth most common hepatic neoplasm in children, after hepatoblastoma, infantile hemangioendothelioma, and HCC.¹⁴³ It usually occurs in older children, 6 to 10 years of age, and 90% of patients are younger than 15 years.¹⁴⁵ The incidence is almost the same in males and females.

The usual presenting symptoms are pain and abdominal mass, with fever, jaundice, weight loss, and gastrointestinal

Figure 87-35 Angiosarcoma. Gadolinium-enhanced MR images obtained in the arterial (A) and portal venous (B) phases demonstrate the replacement of the liver parenchyma with numerous nodules. There is also an angiosarcoma in the spleen.

Figure 87-36 Undifferentiated embryonal sarcoma. **A** and **B.** Undifferentiated embryonal sarcoma in a 22-year-old woman. Portal venous phase contrast-enhanced CT scan (**A**) shows a 10-cm-diameter cystic lesion with septa in the right lobe of the liver. Note the calcifications (arrow) within the mass. Specimen photograph (**B**) shows that the mass has predominantly solid components (arrows) with coexisting hemorrhagic areas. **C** and **D.** Undifferentiated embryonal sarcoma in a 36-year-old woman. T2-weighted MR image (**C**) shows a mass in the right lobe of the liver. The solid portions of the mass (arrowheads) are hyperintense relative to normal liver tissue, and the cystic portions (arrow) have signal intensity similar to that of water. Delayed phase gadolinium-enhanced T1-weighted MR image (**D**) shows heterogeneous enhancement of the solid portions of the lesion (arrow). (From Koenraad J, Mortelet KJ, Ros PR: Cystic focal liver lesions in the adult: Differential CT and MR imaging features. *RadioGraphics* 21:895–910, 2001.)

complaints found less commonly. α -Fetoprotein levels are usually not elevated.

RADIOLOGIC FINDINGS

Plain Radiography

Abdominal radiographs demonstrate a large, usually noncalcified mass in the upper abdomen associated with displacement of adjacent structures and elevation of the diaphragm on the right side. Calcification, although rare, may occur, with small, punctate chunks of calcium seen within the solid portions of this tumor.¹⁴⁵

Nuclear Medicine

On liver sulfur colloid scans, UES is usually a well-defined intrahepatic defect. Blood pool studies demonstrate no early uptake or delayed filling, corresponding to the hypovascular nature of this tumor.¹⁴⁵ Bone scintigraphy and gallium scans demonstrate no uptake by UES.¹⁴⁵

Ultrasound

On sonograms, the appearance of UES ranges from a multiseptate cystic mass to an inhomogeneous, predominantly

echogenic solid mass. The cysts range in size from a few millimeters to several centimeters, corresponding to the cystic changes seen grossly.¹⁴⁵ In a review of 28 cases of UES, all tumors were predominantly solid.¹⁴⁶

Computed Tomography

On CT scans, UES appears as a hypodense mass resembling old intrahepatic hemorrhage or a biloma¹⁴⁷ (see Fig. 87-36A). Calcification is a rare feature.¹⁴⁶ Septa are seen as dense bands within the cystic tumor, corresponding to solid portions. If there is a pseudocapsule, a thin rim of dense tissue may surround the predominantly cystic tumor. On contrast-enhanced CT images, heterogeneous enhancement is present in the solid, usually peripheral portions of the mass, especially on delayed images.^{108,129}

Angiography

Angiographic studies demonstrate a large hypovascular to avascular mass. Abnormal vessels as well as hypervascular portions can be seen in the solid component of UES. Intratumoral aneurysms, arteriovenous shunting, pooling of contrast medium, and arterial encasement can be found in tumors with a sizable solid component.

Magnetic Resonance Imaging

On MRI, UES has signal characteristics similar to cerebrospinal fluid, with high signal on T2-weighted images and low signal on T1-weighted images.¹⁴⁶ In addition, foci of high signal intensity are seen on T1-weighted images corresponding to hemorrhage.¹⁴⁶ If present, the pseudocapsule and septations are of low signal intensity on both T1- and T2-weighted images. The enhancement pattern of UES on postcontrast MR images is parallel to that on CT images (see Fig. 87-36D).

Epithelial Hemangioendothelioma

PATHOLOGIC FINDINGS

Epithelial hemangioendothelioma (EHE) is a rare malignant hepatic neoplasm of vascular origin that develops in adults. It should not be confused with infantile hemangioendothelioma, which occurs predominantly in young children.

INCIDENCE AND CLINICAL PRESENTATION

EHE is usually discovered incidentally, although jaundice, liver failure, and occasionally rupture with hemoperitoneum may be present.¹⁴⁸ It is more common in women than in men.

In gross appearance, the tumors are often multiple and are composed of neoplastic cells that infiltrate the sinusoids and intrahepatic veins. The prognosis of EHE is much more favorable than that of angiosarcoma; extrahepatic metastases occur in only one third of the reported cases.¹⁴⁸ It appears that the biologic behavior of this tumor is related to its matrix, including inflammation, sclerosis, and calcification.

RADIOLOGIC FINDINGS

EHEs appear as multiple nodules that grow and coalesce, forming large confluent masses. This lesion usually develops in the periphery of the liver and commonly shows calcifications corresponding to the fibrotic nature of this tumor.¹⁴⁹ The calcifications are visible on plain radiographs in 15% of cases.¹³⁸

On sonography, EHE is primarily hypoechoic.^{138,150} On CT scans, the full spectrum of growth may be seen from multiple nodules to large confluent masses.¹³⁸ On unenhanced CT scans, EHE is of low attenuation, corresponding to myxoid stroma.¹³⁸ Portions of these large, low-attenuation masses become isodense after administration of contrast material, so it is often easier to identify the extent of the disease on unenhanced scans. With extensive involvement, compensatory enlargement of the uninvolved portions of the liver is seen.¹³⁸ On angiographic examination, the tumor may be hypervascular, hypovascular, or avascular, depending on the extent of hyalinization and sclerosis within the tumor.^{138,150} Invasion of hepatic veins may be seen.¹³⁸

The MRI features of EHEs are similar to the CT appearances, and either peripheral nodules or larger confluent lesions are seen.^{151,152} The tumors are hypointense on T1- and hyperintense on T2-weighted images, although a hypointense center may be seen on both sequences corresponding to calcification, necrosis, and hemorrhage.¹⁵² After intravenous administration of Gd-DTPA, moderate peripheral enhancement and delayed

central enhancement are seen.¹⁵² MRI also demonstrates invasion of the portal veins by the tumor.¹⁵² With the exception of calcification, MRI demonstrates the internal architecture of EHE better than CT does.¹⁵²

Other Mesenchymal Sarcomas (Leiomyosarcoma, Malignant Fibrous Histiocytoma)

PATHOLOGIC FINDINGS

Primary tumors arising in mesenchymal elements of the adult liver are extremely rare. They include angiosarcoma, fibrous sarcoma, rhabdomyosarcoma, leiomyosarcoma, and malignant fibrous histiocytoma.¹⁵³⁻¹⁵⁵ These sarcomas of the liver are usually large, solid, smoothly lobulated tumors and on cut surface show fibrous septa or central necrosis and hemorrhage.

INCIDENCE AND CLINICAL PRESENTATION

Primary leiomyosarcoma of the liver is rare, with few cases reported in the literature.¹⁵³ The majority of patients are adults with an average age at discovery of 57 years. Leiomyosarcomas grow slowly, with slowly evolving clinical abnormalities present for several months. Survival ranges from several months to years.

RADIOLOGIC FINDINGS

On CT scans, both leiomyosarcoma and malignant fibrous histiocytoma have a similar appearance: a large, noncalcified, hypodense, homogeneous mass that exhibits inhomogeneous peripheral enhancement after administration of the contrast agent.^{156,157} Ultrasound demonstrates a variable appearance from hyperechoic to isoechoic and hypoechoic patterns.

Lymphoma

PATHOLOGIC FINDINGS

Hepatic lymphoma can be either primary or secondary and can occur in both Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL). The majority of lymphomas of the liver are secondary; primary lymphoma is rare.¹⁵⁸ However, secondary lymphoma of the liver is found in more than 50% of patients with HL or NHL.^{159,160}

Nodular and diffuse forms of hepatic lymphoma are seen. HL occurs more often as miliary lesions than as masses. Early in the disease, liver involvement is microscopic, but with time, small nodules a few millimeters to several centimeters in size develop.¹⁶¹ HL of the liver is almost invariably associated with splenic involvement, and the likelihood of hepatic disease is greater if there is extensive splenic disease.^{162,163}

In patients with HL, a Reed-Sternberg variant type of cell is accepted as evidence for liver involvement. Typical Reed-Sternberg cells are rarely identified, particularly in biopsy specimens. In NHL, the lymphocytic form tends to be miliary whether the large cell or histiocytic varieties are nodular or tumoral.¹⁶⁴ In both HL and NHL, initial involvement is seen in

the portal areas because this is where the majority of the scant lymphatic tissue of the liver is found.

INCIDENCE AND CLINICAL PRESENTATION

Primary hepatic lymphoma occurs most commonly in middle-aged white men.¹⁶⁵ Organ transplant recipients and patients with acquired immunodeficiency syndrome are at high risk for development of hepatic lymphoma. Patients usually present with right upper quadrant pain, hepatomegaly, or a tender upper abdominal mass. Hepatomegaly may be present in an uninvolved liver, and a diffusely infiltrated liver can be of normal size.¹⁶⁶

RADIOLOGIC FINDINGS

Plain Abdominal Radiography

Plain abdominal radiography may demonstrate hepatomegaly in cases in which the liver is markedly enlarged. Calcifications are not detected in untreated hepatic lymphoma. Barium studies may demonstrate other involved areas in the gut.

Nuclear Medicine

Lymphomas may be manifested as focal defects on technetium Tc 99m sulfur colloid scans or with diffusely inhomogeneous hepatic uptake. Gallium citrate is taken up by normal liver tissue and lymphoma, and the usefulness of the technique in the diagnosis of hepatic lymphoma is therefore questionable. However, it may help confirm areas of liver involvement seen by other imaging techniques and may have a role in assessing response to therapy.^{165,167} On occasion, areas of increased uptake in relation to normal liver can be identified.

Ultrasound

On ultrasound studies, hepatic lymphoma appears as a hypoechoic mass or masses in the tumoral form of the disease. In the diffuse form, the echogenicity of the hepatic parenchyma may be normal or the overall architecture of the liver may be altered.¹⁶⁵ If there is bleeding within the lymphoma deposit, true cystic ultrasonographic characteristics may be detected.¹⁶⁸

Computed Tomography

CT is currently the preferred imaging method for evaluating lymphoma of the liver, with a specificity of almost 90% and a sensitivity of almost 60%.^{169,170}

Secondary hepatic lymphoma most commonly is manifested as multiple well-defined, large, homogeneous low-density masses (Fig. 87-37). Areas of diffuse infiltration by lymphoma causing hepatomegaly may not be distinguishable from normal liver tissue by CT. Frequently, additional areas of involvement may be noted in the spleen, lymph nodes (para-aortic, celiac, and periportal), and kidneys.¹⁷⁰

Angiography

On angiography, primary and secondary lymphomatous liver masses are usually hypovascular or avascular. There may be arterial displacement; however, encasement is not noted. In the capillary phase, the tumor mass is relatively hypolucent.

Figure 87-37 Hepatic lymphoma. Contrast-enhanced CT scan shows a lesion with heterogeneous low attenuation in the right hepatic lobe.

Magnetic Resonance Imaging

Hepatic lymphoma is hypointense compared with normal liver on T1-weighted images and hyperintense on T2-weighted images. After intravenous administration of contrast material, transient perilesional enhancement of focal hepatic lymphoma deposits has been reported. However, these tumors generally remain hypointense during the dynamic study as a result of their poor vascularity.^{58,171} Although it is easy to distinguish normal liver, the difference in relaxation times of lymphoma and metastases is not significant. Diffuse hepatic lymphoma is more readily detectable by CT than by MRI. Although some authors indicate that MRI may be slightly more sensitive than CT for all forms of hepatic involvement, this has not been completely proved.¹⁷²

Metastases

PATHOLOGIC FINDINGS

Gross Pathology

Metastases vary in size, consistency, uniformity of growth, stromal response, and vascularity (Fig. 87-38). They can be infiltrative or expansive. All these factors depend on the primary source and mode of metastasis. The gross morphologic patterns of the major liver metastases are described in Table 87-5.^{173,174}

Metastatic adenocarcinomas from the gallbladder and colon often have a slimy cut surface because of mucin production. Tumors that are expanding and massive, such as colon cancer metastases, often have central liquefactive necrosis. Metastases that have significant necrosis or fibrosis can umbilicate the surface of the liver capsule, which is a helpful diagnostic feature because HCCs rarely cause umbilication.^{173,174}

Poorly differentiated tumors such as seminomas, oat cell carcinomas, NHLs, and undifferentiated sarcomas tend to have a uniformly soft, “fish flesh–like” consistency. Squamous cell carcinomas have a granular and caseous central portion that lacks the shiny appearance of most adenocarcinomas.^{173,174}

Individual metastases in the same liver can vary greatly in appearance because of differences in blood supply, hemorrhage,

Figure 87-38 Hepatic metastases: pathology. **A.** Multiple metastases from breast cancer are present in both lobes of the liver. **B.** Cut section shows multiple large metastases from lung cancer. **C.** Photomicrograph shows normal liver on the left and gastric cancer metastases on the right side of the image.

TABLE 87-5	Morphologic Patterns of Metastatic Tumors to Liver	
Pattern	Site	
Expanding massive (solitary with satellites or multiple foci)	Colon, gallbladder, testis	
Uniformly nodular	Lung, melanoma, pancreas	
Infiltrative massive	Lung, breast, pancreas, bladder, melanoma	
Uniformly multifocal	Breast, pancreas, lung, melanoma	
Diffuse	Breast, pancreas, lymphomas	
Surface spreading	Colon, ovary, occasionally stomach	
Miliary	Prostate, occasionally any	
Mixed or indeterminate	Any	

Modified from Edmondson HA, Craig JR: *Neoplasms of the liver*. In Schiff L, Schiff ER (eds): *Diseases of the Liver*, 8th ed. Philadelphia, JB Lippincott, 1987, pp 1109–1158.

cellular differentiation, fibrosis, and necrosis. This variable pattern is particularly common in the vascular metastases carcinoid, renal cell carcinoma, choriocarcinoma, and bronchogenic carcinoma.^{173,174}

An unusual zone of venous stasis up to 1 cm in size is observed in approximately 25% of affected livers. This zone is uniformly circumferential, and either all or none of the metastatic foci have this finding. This phenomenon is seen most commonly with bronchogenic cancer and least commonly with colon cancer and has important implications for imaging and enhancement with contrast material.^{173,174}

Microscopic Pathology

Most metastases maintain the microscopic features of the primary tumor, including the degree of stromal growth. Metastatic carcinomas of the pancreas and breast incite an intense fibrous or sclerosing reaction around the tumor acini, leading to fibrous scar formation. Oat cell carcinoma intermingles with the liver plates, blending in with the hepatocytes. In fact, some tumors with no organoid pattern at the primary site (e.g., bronchogenic carcinoma, bladder carcinoma) may retain the pattern of the sinusoidal bed and simulate a ductal liver neoplasm. In colon cancer metastases, a thin collagenous pseudocapsule is often situated between the tumor margin and compressed liver but does not surround individual tumor glands.^{173,174}

Approximately 7% to 15% of patients with metastatic liver disease have tumor thrombi that occlude the portal or hepatic veins. Metastases that penetrate the large portal veins disseminate throughout peripheral portal branches. When the hepatic veins are penetrated, pulmonary metastases can develop.^{173,174}

In the presence of mucin, necrosis, and phosphatase activity, metastases can develop calcification that is detectable radiographically.^{175,176} This is particularly common in metastases from mucinous adenocarcinomas of the colon, pancreas, and stomach.

INCIDENCE AND CLINICAL PRESENTATION

Metastases (Table 87-6) are by far the most common cause of malignant focal liver lesions, outnumbering primary malignant tumors by a factor of 18 : 1. The liver is second only to regional lymph nodes as a site of metastatic disease, and approximately 25% to 50% of all patients who die of cancer have liver

TABLE 87-6 Most Common Nonlymphoma Hepatic Metastases

Tumor	No. of Primary Tumors	No. with Metastases	Percentage with Metastases
Lung	682	285	41.8
Colon	323	181	56.0
Pancreas	179	126	70.4
Breast	218	116	53.2
Stomach	159	70	44.0
Unknown primary	102	59	57.0
Ovary	97	47	48.0
Prostate	333	42	12.6

Thyroid	70	12	17.1

Modified from Edmondson HA, Craig JR: *Neoplasms of the liver*. In Schiff L, Schiff ER (eds): *Diseases of the Liver*, 8th ed. Philadelphia, JB Lippincott, 1987, pp 1109–1158.

metastases at autopsy. Colon (42%), stomach (23%), pancreas (21%), breast (14%), and lung (13%) are the most common primary neoplasms. A silent primary with hepatic metastasis most often occurs in carcinoma of the pancreas, stomach, and lung. The highest percentage of liver metastases occurs in primary carcinoma of the gallbladder, pancreas, colon, and breast; the lowest percentage occurs in prostate cancer.

Approximately 50% of patients who die with metastatic carcinoma of the liver have some hepatic signs or symptoms. Hepatomegaly (31%) is the most common finding, followed by ascites (18%), jaundice (14.5%), and varices (1%). Liver function tests are notoriously unreliable for detection of metastases; results are normal in 25% to 50% of patients with metastases and can be abnormal in any number of conditions, such as parenchymal tumor replacement, tumor obstructing the intrahepatic or extrahepatic bile ducts, or chemotherapy hepatotoxicity. For this reason, imaging is the key to both the diagnosis and serial follow-up of liver metastases.^{175,177} In addition, cross-sectional imaging techniques now have a unique and important role in the management of patients with hepatic metastases from colorectal cancer. Many of these patients have good survival rates of 20% to 40% at 5 years if resection of liver metastases is performed. However, the preoperative evaluation of these patients is vital in selecting those who will benefit from surgery. Accurate assessment of the presence, extent, and number of liver metastases and the delineation of extrahepatic disease are requirements of any imaging technique.¹⁷⁸

RADIOLOGIC FINDINGS

Plain Radiography

Plain abdominal radiographs in patients with metastatic disease most commonly show normal findings. Nonspecific findings include hepatomegaly, ascites, and splenomegaly, which may be due to humoral factors, tumor, or portal hypertension.^{179,180}

BOX 87-3 METASTATIC LIVER TUMORS THAT MAY CALCIFY

Mucinous carcinoma of the colon, stomach, and pancreas
Islet cell pancreatic tumor
Leiomyosarcoma, osteogenic sarcoma, rhabdomyosarcoma, chondrosarcoma
Papillary serous ovarian cystadenocarcinoma
Malignant melanoma
Pleural mesothelioma
Neuroblastoma
Embryonal tumor of the testis
Bronchogenic carcinoma
Breast cancer

Calcification (Box 87-3) is a more specific sign but is insensitive (<1%) except in small children with metastatic neuroblastoma, in whom the sensitivity approaches 25%. Colloid carcinomas of the colon or stomach most commonly cause calcification that has been described as stippled, amorphous, flaky, punctate, granular, or poppy seed-like. The pattern of calcification, however, seldom indicates whether the tumor is primary or metastatic, and even differentiation from benign disease may be difficult. When there is a progressive increase in the size and number of calcifications accompanied by hepatomegaly, the diagnosis of neoplasm is nearly certain. Calcification may also occur in focal areas of metastasis after radiation therapy or chemotherapy.

Nuclear Medicine

Metastases typically are manifested as focal defects on both sulfur colloid and hepatobiliary scintiscans.¹⁸¹⁻¹⁸⁴ They are, in fact, the most common cause of focal “cold” liver lesions. Most often, multiple round focal defects of relatively uniform size are seen. The scintigraphic pattern, however, depends on the primary tumor type, stage of disease, and presence of underlying hepatic disease, such as cirrhosis, acute or chronic hepatitis, or steatosis. When only a single defect is seen, it must be differentiated from a normal variant, cyst, abscess, or intrahepatic gallbladder. Multiple defects make the diagnosis of metastases likely, but multiple cysts, hemangiomas, or abscesses may occasionally have the appearance.^{185,186}

Some tumors (leukemia, lymphoma) may infiltrate the liver diffusely, whereas others (breast and oat cell carcinoma) cause numerous small focal nodules. In both of these circumstances, hepatomegaly or diffuse heterogeneity of uptake or both may be seen. Colon cancers commonly produce large, often solitary defects.^{185,186}

Whereas nuclear medicine is no longer routinely used for the detection of hepatic metastatic lesions, PET with ¹⁸F-FDG has emerged as a sensitive tool for the detection of liver metastases from colorectal primaries (Fig. 87-39).¹⁸⁷ ¹⁸F-FDG is a glucose analogue that is metabolized more rapidly in tumor cells than in normal cells, resulting in increased uptake in malignant lesions.¹⁸⁷ However, PET has important limitations. The spatial resolution is poor, so complementary anatomic information from cross-sectional imaging techniques such as CT is necessary for evaluation of PET findings.¹⁷⁸ PET/CT is an efficient tool to solve this problem by means of combining the metabolic imaging and spatial localization advantages of PET and CT. A

Figure 87-39 Hepatic metastases: PET/CT. **A.** Axial, unenhanced CT shows no mass. **B.** PET image at the same level shows uptake of ^{18}F -FDG in the right lobe. **C.** Fused image provides precise localization of the colon cancer metastasis. **D.** Whole body PET image shows the solitary hepatic metastasis.

second limitation is the ^{18}F -FDG uptake by inflammation, which makes clinical correlation necessary to assess the significance of PET findings.¹⁸⁸

^{18}F -FDG PET has been shown to be valuable in the response assessment of liver metastases undergoing systemic or local interventional therapy. ^{18}F -FDG PET is superior to CT in the assessment of radiofrequency ablation response by being able to distinguish between a marginal zone of reactive hyperperfusion, which is frequently seen at the rim of metastases on contrast-enhanced CT after radiofrequency ablation, and residual viable tumor tissue.¹⁸⁹⁻¹⁹²

After radiofrequency ablation treatment, most metastases that were persistently ^{18}F -FDG PET positive recurred within the follow-up time of 16 months, whereas metastases that were found to be ^{18}F -FDG PET negative within 3 weeks after treatment were less likely to relapse.¹⁹³ Recently, regarding the patients with liver metastases from breast cancer, the only independent predictive factor for patient survival was identified as a change in maximal standardized uptake value between the preinterventional stage and 3 months after selective internal radiation therapy.¹⁹⁴ In respect to this, it can be said that after therapy, functional MRI and PET can be useful for providing complementary information on tumor tissue viability. A study comparing diagnostic performance of fused ^{18}F -FDG PET and Gd-EOB-DTPA-enhanced MRI retrospectively versus

stand-alone Gd-EOB-DTPA-enhanced MRI and integrated PET/CT for liver lesion detection revealed that PET/MRI was significantly more accurate than PET/CT, providing significantly greater confidence for discrimination between benign and malignant liver lesions and representing a perfect test for the detection of hepatic lesions larger than 1 cm.¹⁹⁵ According to the same study, comparison of stand-alone Gd-EOB-DTPA-enhanced MRI and PET/MRI did not reveal significant change in sensitivity or specificity. Interestingly, the performances of both PET/MRI and Gd-EOB-DTPA-enhanced MRI were better than PET/CT in the detection and characterization of lesions smaller than 1 cm.¹⁹⁵

It seems that especially for detection of small hepatic lesions, compared with CT, MRI compensates for the drawbacks in PET better (Figs. 87-40 and 87-41)¹⁹⁶ and enhances lesion discrimination.¹⁹⁵ However, PET/MRI does not seem to have any benefits over MRI alone.²⁰

Ultrasound

Ultrasound has a diagnostic sensitivity of more than 90% in the detection of metastases.¹⁹⁷ In the absence of complications, such as hemorrhage, infection, or necrosis, focal metastatic liver disease is manifested with five basic sonographic patterns (Fig. 87-42): hypoechoic, bull's-eye or target pattern, calcified, cystic, and diffuse. Although there is no consistent correlation between

Figure 87-40 Hepatic metastases: PET/CT and PET/MRI. Metastatic colon cancer in a 76-year-old man. Axial CT (A), ^{18}F -FDG PET (B), and fused PET/CT (C) images demonstrate two hypermetabolic low-attenuation lesions in the dome of the liver. The metastatic lesions are well appreciated on T2-weighted spectral attenuated inversion recovery image (D). ^{18}F -FDG PET image (E) and fused PET/MRI axial image (F) delineate the hypermetabolic activity.

sonographic appearance and primary tumor type, certain generalities can be made (Box 87-4).¹⁹⁷⁻²⁰³

Hyperechoic Metastases. These usually arise from colon cancers and other gastrointestinal neoplasms. Vascular metastases from islet cell tumors, carcinoid, choriocarcinoma, and renal cell carcinoma tend to be echogenic as well.¹⁹⁸ They are echogenic because of numerous interfaces arising from the abnormal vessels.

Bull's-Eye or Target Pattern. The anechoic, thin, poorly defined halo that often surrounds solid liver metastases is most often a result of peritumoral compression of normal parenchyma and less often a result of tumor infiltrating into

the surrounding parenchyma. Its presence usually indicates an aggressive tumor.^{204,205} This is frequently seen in metastases from bronchogenic carcinoma.

Hypoechoic Metastases. These lesions tend to be hypovascular and highly cellular with few internal interfaces. Lymphoma, particularly when it is associated with acquired immunodeficiency syndrome, can be manifested with multiple hypoechoic deposits. More commonly, lymphoma is diffusely infiltrating.^{198,199}

Cystic Metastases. Cystic metastases usually develop in patients with primary neoplasms that have a cystic component: cystadenocarcinoma of the pancreas and ovary and mucinous

Figure 87-41 Hepatic metastasis: PET/CT and PET/MRI. Metastatic colon cancer in a 60-year-old man. Coronal CT image (A) demonstrates a subtle segment V lesion, further depicted on ^{18}F -FDG PET (B) and fused PET/CT (C) images. T2-weighted spectral attenuated inversion recovery image (D) better delineates the metastasis, with associated hypermetabolic uptake seen on ^{18}F -FDG PET (E) and fused PET/MRI (F) images.

carcinoma of the colon.²⁰⁵ Indeed, these lesions may resemble benign cysts on CT scans. Ultrasound, however, can usually reveal certain differentiating features: septa, mural nodules, debris, fluid-fluid levels, and mural thickening. When the central portion of a liver metastasis undergoes extensive necrosis, sonolucent metastases with low-level echoes and an irregularly thickened wall may be seen.²⁰⁶

Calcified Metastases. These metastases are relatively distinctive because of their marked echogenicity and acoustic shadowing (see Box 87-3). Mucinous adenocarcinoma of the colon is the

most common primary neoplasm associated with calcified liver metastases.^{207,208}

Diffuse Infiltration. This diffuse permeative infiltration is the most difficult sonographic pattern to be appreciated because the tissue texture is diffusely inhomogeneous, without the presence of well-defined masses. Diagnosis is further compromised in the presence of cirrhosis and fatty infiltration.^{198,209}

Contrast-enhanced ultrasound shows lesion blood flow in metastases as a reflection of the vascularity of the primary

Figure 87-42 Hepatic metastases: spectrum of sonographic findings. **A.** Hyperechoic metastases are seen on this sagittal scan of the left hepatic lobe in a patient with carcinoid tumor. **B.** Bull's-eye lesions are present on this axial scan in a patient with metastatic lung cancer. **C.** Hypoechoic metastases are demonstrated in this patient with pancreatic cancer. There is a pleural effusion as well. **D.** Cystic metastasis with multiple fine internal echoes is present in this patient with mucinous ovarian carcinoma. **E.** Calcified metastases are seen in this patient with mucinous colon carcinoma. **F.** Hypervascular liver metastases in a 60-year-old man with previously resected retroperitoneal sarcoma. Early arterial phase ultrasound image (**F**) obtained 20 seconds after contrast material injection shows a large lesion with heterogeneous and mostly peripheral (nonglobular) enhancement (large arrows). Two small lesions remain hypoechoic (small arrows). (**F** from Catalano O, Nunziata A, Lobianco R, et al: *Real-time harmonic contrast material-specific US of focal liver lesions*. *RadioGraphics* 25:333–349, 2005.)

tumor.³⁹ Because of this, considerable variation is seen during the arterial phase enhancement. Hypervascular metastases may reveal enhancement features that overlap with those of HCC. Hypovascular metastases mostly show a slight signal enhancement with a marginal emphasis (halo sign, rim sign).⁴⁰ Fortunately, regardless of their appearance during the arterial phase, metastases have consistently shown less enhancement than the liver during the portal venous phase of contrast-enhanced ultrasound.

Computed Tomography

On CT scans, metastases can be hyperdense, isodense, hypodense, hypodense with peripheral enhancement, cystic, complex, calcified, or diffusely infiltrating (Figs. 87-43 to 87-46). The CT appearance depends on tumor size and vascularity, the degree of hemorrhage and necrosis, and the quality of the intravenous contrast material bolus. Thus, individual metastatic lesions within the liver can have

different CT findings, and metastases from different cell types can appear identical.²¹⁰⁻²¹⁴

Hyperdense metastases (see Fig. 87-44) are uncommon. These lesions are usually hypervascular (Box 87-5) and enhance rapidly and diffusely, becoming isodense with normal liver. These lesions may be difficult to visualize on contrast-enhanced CT scans obtained during the portal venous phase of enhancement. Hypervascular lesions may also occasionally be seen as hypoattenuating lesions on portal venous phase images.²¹⁵

Islet cell tumors are among the most common of the very hypervascular metastases. Breast carcinoma, carcinoid,

melanoma, thyroid carcinoma, and renal cell carcinoma also result in hypervascular metastases.²¹⁶

The majority of metastases are hypodense (see Fig. 87-45) with an attenuation between that of water and that of normal liver. These lesions are usually hypovascular, and intravenous contrast medium increases their conspicuity by increasing the density of normal liver. These lesions are best depicted during the portal phase of enhancement (60 seconds after intravenous administration of contrast material).^{215,217} Colon, lung, prostate, gastric, and transitional cell carcinoma are the most common tumors that appear as hypovascular liver metastases.²¹⁸

On the delayed phase images, metastases are often isoattenuating. Some metastases will show hypoattenuating peripheral areas surrounding an enhanced center on delayed images. This appearance is thought to represent contrast material washing out of the viable tumor periphery while remaining in the extracellular space of the center.²¹⁹

Melanoma
 Carcinoid
 Pancreatic islet cell tumor
 Choriocarcinoma
 Pheochromocytoma
 Breast cancer
 Thyroid carcinoma
 Renal cell carcinoma

Certain metastases may be cystic, having an attenuation less than 20 HU. Ultrasound may be needed to differentiate these lesions from simple cysts. Calcifications are also well demonstrated on CT scans.

Rim enhancement (see Fig. 87-46) of a hypodense metastasis represents a vascularized viable tumor periphery contrasted with a hypovascular or necrotic center.^{210,213}

Unless the size or contour of the liver is altered, diffusely infiltrating metastases can be difficult to appreciate. Diagnosis is also difficult in patients with cirrhosis and hepatic steatosis.

In these cases, MRI can be useful in appreciating the tumor nodules.

The borders of hepatic metastases can be sharp, ill-defined, or nodular, and their shape may be ovoid, round, or irregular.

Magnetic Resonance Imaging

The T1 and T2 relaxation times of liver metastases vary considerably, depending on the primary tumor, degree of necrosis, hemorrhage, and vascularity. Nevertheless, the T1 and T2 relaxation times of most liver metastases (Fig. 87-47) are longer than those of normal liver and shorter than those of simple cysts or hemangiomas.²²⁰⁻²²⁸ Five major morphologic patterns have been described for metastases on MR images.²²⁹

Doughnut. On T1-weighted images, metastases, because of their long T1 relaxation time, are manifested as a low signal intensity mass containing a distinct central region of even lower signal intensity. This pattern is usually seen with larger lesions and those that are prone to undergo necrosis. Metastases that contain considerable mucin, fat, subacute hemorrhage, or melanin, however, may have a relatively high signal intensity on T1-weighted images. High signal intensity has also been observed in carcinoids with hemorrhage.²²⁹

Target. On T2-weighted images, some metastases are manifested with a central smooth or irregularly rounded area of high signal intensity surrounded by a ring of tissue with a somewhat

weaker signal intensity. This pattern is also seen in lesions that are large and tend to undergo necrosis.²²⁹⁻²³¹

Amorphous. These metastases have variable increased signal intensity with inhomogeneous and featureless contents. The outer margins tend to be round and indistinct.

Halo. These masses have a distinct but not necessarily smooth circumferential rim of high signal intensity. The rim varies in thickness from 2 to 10 mm and encircles a lesion of somewhat lower signal intensity. The lower signal intensity may reflect the presence of fibrosis, coagulative necrosis, and mucin. This halo is probably a manifestation of greater water content than in adjacent normal liver parenchyma, perhaps reflecting an edematous reaction incited by tumor cell infiltration. Alternatively, it may reflect a viable tumor. Therefore, the peripheral zone of hyperintensity should be assumed to represent tumor for the purposes of surgical planning and estimating tumor volume. Some 50% of colon cancer metastases have some central hypointensity.²²⁹⁻²³¹

Light Bulb. These lesions are smooth, sharply defined, and round or elliptic. The contents have high signal intensity, similar to that of gallbladder, cerebrospinal fluid, cysts, and hemangiomas. In these cases, the high signal intensity on T2-weighted images is attributed to either fluid contents or considerable blood flow. In metastases, this may be due to complete tumor necrosis and liquefaction or a hypervascular mass. The light

Figure 87-47 Liver metastases: MRI features.

Most metastases have prolonged T1 and T2 relaxation times compared with normal liver. Thus, these lesions have low signal intensity on T1-weighted images (A) and high signal intensity on T2-weighted images (B). There are exceptions, such as metastatic melanoma (C), in which the lesions have high signal intensity on T1-weighted images because of the presence of hemorrhage, mucin, or paramagnetic contents such as melanin. (C courtesy Jay P. Heiken, MD, St. Louis, MO.)

bulb sign has been described in cystic neoplastic metastases, pheochromocytoma, carcinoid, and islet cell tumor.²²⁹⁻²³²

Role of Magnetic Resonance Imaging

The introduction of hepatic resection as a potentially curative treatment for patients with liver metastases from colorectal primaries has created major challenges for MRI. The preoperative assessment of these patients requires accurate delineation of the precise number and location of metastases and their relationship to adjacent vascular structures. Also, because benign liver lesions such as cysts and hemangiomas are relatively common, imaging techniques must be able to distinguish between benign and malignant lesions with a high degree of specificity.²³³ For the performance of MRI to be improved in this clinical context, numerous different sequences and contrast agents have been evaluated. The use of Gd-DTPA in the detection of liver metastases has been disappointing, and no clear benefit of using dynamic gadolinium-enhanced sequences over unenhanced T1-weighted images has been demonstrated at 1.5T.²³⁴ After the intravenous administration of contrast material with dynamic imaging (Fig. 87-48), enhancement patterns of the hepatic metastases are similar to those on CT. Hypervascular metastases show marked early enhancement as a continuous ring that on later images fills in centrally, or they may show early uniform enhancement (Fig. 87-49). During the portal venous phase, hypervascular metastases may become isointense or hypointense (Fig. 87-50). Hypovascular metastases are seen as hypointense masses that may have an enhancing peripheral rim best seen during the arterial phase. Progressive centripetal fill-in may occur on delayed phases.

Several studies have evaluated the accuracy of SPIO-enhanced MRI in the detection of liver metastases by use of findings at intraoperative ultrasound and pathologic examination as the "gold standard."²³⁵⁻²³⁷ With use of SPIO, metastatic lesions should appear unenhanced against a negatively enhanced liver.²¹⁹ SPIO-enhanced MRI detected more lesions than unenhanced MRI, percutaneous ultrasound, and contrast-enhanced CT and was comparable to CT arterial portography.^{235,236} Important advantages of SPIO-enhanced MRI are its lack of invasiveness compared with CT arterial portography and the availability of an extended imaging window, allowing greater flexibility in scanning times (Fig. 87-51).²³⁸

With use of hepatobiliary contrast agents such as Gd-EOB-DTPA, hepatic metastases from extrahepatic malignant neoplasms do not enhance in the hepatocellular phase because of

lack of functioning hepatocytes or bile ducts, and they typically appear uniformly hypointense relative to normal liver (Fig. 87-52). On occasion, at the interface between a metastasis and normal liver parenchyma, a thin rim of hyperintensity can be seen that presumably represents a perilesional biliary reaction, compressed normal hepatic parenchyma, or a combination of the two.⁶⁸

Gd-EOB-DTPA appears to be suitable not only for detecting very small metastases less than 1 cm but also in differentiating them from FNH and simple cysts.^{239,240} In several studies, it is reported that with the use of Gd-EOB-DTPA, more liver metastases are depicted, and also lesion characterization and diagnostic confidence are improved.^{240,241}

The usefulness of diffusion-weighted imaging in the detection of liver metastases compared with unenhanced and dynamic liver-specific contrast-enhanced MRI has been demonstrated by several studies. Lesion conspicuity of hemangiomas and metastases is significantly higher with respiratory triggered diffusion-weighted imaging at low b values compared with conventional unenhanced MRI because of an excellent lesion-to-liver contrast and suppression of background signals from vessels.²⁴² However, diffusion-weighted imaging alone is not useful because it is susceptible to motion artifacts that obscure lesions, and difficulty arises for image interpretation.²⁴³ Breath-hold or respiratory triggered diffusion-weighted imaging has a significantly higher overall lesion detection rate compared with conventional T2-weighted MRI.²⁴⁴ Especially in considering small metastases less than 10 mm, respiratory echo planar diffusion-weighted imaging is more sensitive in detection compared with conventional MRI with and without contrast.²⁴⁵ Low lesion-to-liver contrast and the interfering bright signal from intrahepatic vessels hinder lesion detection on T2 turbo spin-echo sequences. Lesion conspicuity with diffusion-weighted imaging is excellent, and limitation of the diffusion-weighted imaging sequence is predominantly referred to lesion characterization rather than to lesion detectability.²⁴⁶

Angiography

Angiography is no longer used to diagnose liver metastases but is performed to provide a vascular road map for the surgeon and to guide intra-arterial therapy.²⁴⁷ Because metastases are almost completely supplied by the hepatic artery, injection of the celiac or superior mesenteric artery may show hypervascular tumor circulation early and

Figure 87-48 Liver metastases: ring enhancement on MRI. There are complete rings of lesion enhancement seen in this patient with breast cancer and a solitary metastasis in the left lobe (A) and in a different patient with multiple carcinoid metastases (B).

Figure 87-49 Liver metastasis: MRI findings.

A patient with a hypervascular liver metastasis of a malignant neuroendocrine tumor (arrows). The metastasis is slightly hyperintense on the T2-weighted image (A) and shows strong enhancement on the arterial (B) and late phase (C) images. On the diffusion-weighted image (D), the metastasis shows diffusion restriction and appears hyperintense. It has a low ADC value on the ADC map (E).

hypovascularity during the venous phase as portal blood containing contrast medium perfuses the surrounding normal hepatic parenchyma.²⁴⁷⁻²⁴⁹

Differential Diagnosis— Incidental Mass

Improvements in cross-sectional imaging have led to the detection of more and smaller hepatic lesions. Detection of lesions smaller than 15 mm can be a problem because of their uncertain clinical significance. In one study using CT, a single small (<1.5 cm) lesion was benign in 65% of patients, and two to four tiny lesions were benign in 59% of cases. When the number of lesions increases or an additional large lesion is present, the likelihood of malignancy increases. Even in the presence of extrahepatic malignant disease, 51% of these small lesions are benign. This has important implications for patients with dominant metastases who are being considered for hepatic resection.

The possibility that the other lesions are benign should be considered.²⁵⁰

Metastases are not the only causes of multiple hepatic masses. Abscess, cyst, extramedullary hematopoiesis, multifocal or diffuse HCC, ICAC, angiosarcoma, nodular regenerative hyperplasia, and hemangioma can all be multiple.

Practical Approach to Liver Masses

The evaluation of focal liver masses should be systematic and include both radiologic appearance and clinical information to help narrow the differential diagnosis. The three most important pieces of clinical information in evaluating liver neoplasms are the age and sex of the patient and the presence of extrahepatic malignant disease. In adults, metastases, FLC, FNH, and hepatocellular adenoma are seen in patients younger than 40 years. Metastases, typical HCC, ICAC, angiosarcoma, and hemangioma are most frequently seen in patients older than 50 years. In pediatric patients, the vascular tumors infantile

Figure 87-50 Liver metastasis: MRI findings. A patient with breast cancer. There is a slightly hyperintense metastasis on the T2-weighted image (**A**) that is hypointense on the T1-weighted image (**B**). It shows enhancement on the arterial phase image (**C**), then becomes isointense with the liver on the portal venous phase image (**D**). Finally, on the late phase image (**E**), this metastasis shows rimlike peripheral enhancement while its central parts remain isointense with the liver. Arrow, liver metastasis.

Figure 87-51 MRI of liver metastases with SPIO-enhanced scan. Metastases that are barely visualized on T2-weighted MR image (**A**) can be easily detected after the administration of SPIO (**B**). (Courtesy Dr. Tomoaki Ichikawa, Yamanashi University, Yamanashi, Japan.)

Figure 87-52 Liver metastasis: MRI features. MR images of a patient with breast cancer. On the T2-weighted (A) and arterial phase (B) images, the lesion is not visible. On the late phase image (C), the lesion is somehow suspicious. On the diffusion-weighted image with a b value of 1000 (D), the lesion is clearly depicted. The hepatocellular phase image (E) is in concordance with the diffusion-weighted image. Arrow, liver metastasis.

hemangioendothelioma and hemangioma are seen in the first 6 months of life. Hepatoblastoma usually is manifested in the first 3 years of life, and although it may be present at birth, the peak incidence is at 18 months. Benign mesenchymal hamartoma has an incidence similar to that of hepatoblastoma. Tumors that occur in older children and adolescents include HCC and UES. With regard to sex, malignant primary liver tumors are generally more frequent in men and benign primary tumors in women. Metastases are overwhelmingly more frequent than primary liver neoplasms in both the pediatric and the adult populations. Other significant clinical data include a history of chronic steroid and contraceptive use. Neoplasms related to steroid use include hepatocellular adenoma and, to a

lesser degree, FNH, nodular regenerative hyperplasia, hemangioma, and HCC.

Multiple imaging tests are available for evaluating hepatic neoplasms. Contrast-enhanced dynamic MR and CT imaging and sonography provide important diagnostic clues that can help establish a final diagnosis. In interpreting a hepatic imaging study, the parameters to consider are the presence of single versus multiple masses; calcification; sharpness of contour; presence, absence, or persistence of enhancement; patency of vessels; and extrahepatic extension.

After all these considerations, the radiologist must determine whether a hepatic mass is a nonsurgical lesion. In the adult, the two most common nonsurgical primary tumors

are hemangioma and FNH. All other primary neoplasms of the liver are surgical lesions if they are resectable. Therefore, the two most important determinations the radiologist must make are whether the mass in the liver is hemangioma or FNH and, if it is not, whether the mass is resectable for cure. Metastases, HCC, FLC, ICAC, angiosarcoma, and hepatocellular adenoma are all potentially resectable in the adult. In children, hepatoblastoma, UES, HCC, and mesenchymal hamartoma are all surgical lesions. Infantile hemangioendothelioma does not require surgery if the patient can survive with supportive therapy or embolization until the tumor regresses spontaneously.

Hemangioma has a highly suggestive appearance on ultrasound, CT, MRI, and scintigraphic studies. However, the optimal imaging techniques are dynamic MRI with gadolinium enhancement and contrast-enhanced CT (see Chapter 83). The appearance of FNH on ultrasound, CT, and unenhanced MRI is nonspecific, unless a central scar is present, and overlaps with FLC and hepatocellular adenoma. However, gadolinium-enhanced dynamic MRI and T2-weighted MRI enhanced with SPIO may demonstrate imaging features of FNH that aid in narrowing of the differential diagnosis. FNH shows characteristically dramatic signal loss. The degree of signal loss is greater than in other focal liver lesions, such

as hepatocellular adenoma and metastases, and is a useful diagnostic feature for FNH.²⁵¹

Hepatobiliary contrast agents also play a major role in the diagnostic work-up of liver masses. They can be used to differentiate benign lesions from the malignant ones and most probably to estimate the differentiation degree of HCCs. Nevertheless, hepatocellular phase images are not enough for a correct diagnosis to be made. The extracellular phases (arterial, portal venous, and hepatic venous phases) of MRI with hepatobiliary contrast agents, T2-weighted images, diffusion-weighted images, and in-phase and out-of-phase images are all crucial for a definite diagnosis of the liver masses to be reached.

Finally, the use of percutaneous needle biopsies should be considered for exceptional cases, when noninvasive imaging studies have yielded atypical or inconclusive findings. In general, liver biopsies are devoid of significant risk when they are performed with CT or ultrasound guidance. The material obtained by percutaneous biopsy is sometimes not sufficient for a diagnosis, and an open biopsy should be done.

In summary, the differential diagnosis of a liver neoplasm can be narrowed significantly by use of different imaging and clinical features. In addition, percutaneous biopsy may be useful in further defining tumors without a characteristic imaging appearance.

Tuberculosis

Technologic advances have significantly enhanced the role of radiology in the detection, characterization, and management of focal infectious diseases of the liver. Today, all cross-sectional techniques allow highly accurate detection of focal hepatic infections. Computed tomography (CT) is particularly helpful in revealing the presence of calcifications and gas and in detailing the enhancement pattern.¹ With its multiplanar capacity and sensitivity to small differences in tissue composition, magnetic resonance imaging (MRI) is a useful tool to diagnose and to characterize lesions such as hepatic abscess,

hydatid cyst, and candidiasis. The impact of imaging is particularly dramatic for pyogenic abscess; early diagnosis and imaging-guided percutaneous drainage have markedly reduced both the mortality rates (from 40% to 2% of cases) and the need for surgery.¹ This chapter is a review of the radiologic and pathologic findings in a variety of focal hepatic infections, including abscesses, parasitic diseases, and fungal diseases.

Bacterial (Pyogenic) Hepatic Abscesses

INCIDENCE

Pyogenic liver abscesses are uncommon in Western countries, accounting for 0.1% of hospital admissions and having a prevalence at autopsy series of nearly 1%. There is a slight female predominance, and individuals between 40 and 60 years of age are most often affected.²⁻⁶

PATHOGENESIS

Hepatic abscess can develop by five major routes: biliary—ascending cholangitis from benign or malignant biliary obstruction, choledocholithiasis; portal vein—pyelephlebitis from appendicitis, diverticulitis (Fig. 88-1A), necrotic colon cancer, inflammatory bowel disease, proctitis, infected hemorrhoids, pancreatitis; hepatic artery—septicemia from bacterial endocarditis, pneumonitis, osteomyelitis; direct extension from contiguous organs—perforated gastric or duodenal ulcer, lobar pneumonia, pyelonephritis, subphrenic abscess; and traumatic, from blunt or penetrating injuries. Metastatic tumor nodules can also become abscesses.⁷⁻¹⁴

Before the antibiotic era, pyelephlebitis of the portal vein from seeding by appendicitis and diverticulitis was the most common cause of hepatic abscess.¹⁵ Indeed, appendicitis, which was once responsible for 34% of all pyogenic abscesses, now accounts for less than 2%.¹³⁻¹⁶ Biliary tract disease is now the most common source of pyogenic liver abscess.¹⁵ Obstruction of bile flow allows bacterial proliferation. Through pressurization and distention of canaliculi, portal tributaries and lymphatics are invaded, with subsequent pyelephlebitic abscess formation. Cholecystitis, stricture (benign or malignant), malignant neoplasms, and congenital diseases are common inciting conditions. Approximately 50% of pyogenic abscesses are caused by an anaerobic organism, mixed anaerobic organisms, or mixed anaerobic and aerobic organisms. Facultative gram-negative enteric bacilli, anaerobic gram-negative bacilli, and microaerophilic streptococci are the organisms most often responsible for liver abscesses. *Escherichia coli* is the organism most commonly isolated in culture in adults (Fig. 88-1B).

Staphylococci organisms are most often isolated from hepatic abscesses in children.⁵

PATHOLOGY

Abscesses of biliary tract origin are multiple and in 90% of cases involve both hepatic lobes. Abscesses of portal origin are usually solitary; 65% occur in the right lobe, 12% occur in the left lobe, and 23% are bilateral. This distribution is explained by the streaming effect of mesenteric blood flow in the portal vein.²

CLINICAL FINDINGS

The high morbidity and mortality of hepatic abscesses (50%-70%) before the era of cross-sectional imaging attest to the difficulty of establishing a diagnosis of pyogenic liver abscess on clinical grounds alone. The most common symptoms are fever, malaise, pain, rigors, nausea and vomiting, and weight loss. Tender hepatomegaly is the most common clinical sign, and leukocytosis, elevated serum alkaline phosphatase levels, hypoalbuminemia, and prolonged prothrombin time are the most common laboratory abnormalities. Clearly, these findings are nonspecific, and cross-sectional imaging has proved vital in the prompt diagnosis and management of hepatic abscess, resulting in improved survival.^{2,5,6,17}

RADIOLOGIC FINDINGS

Cholangiography

Ascending cholangitis is the most common cause of pyogenic hepatic abscess, and cholangiography has become an important aid to diagnosis in many cases. Percutaneous transhepatic cholangiography and endoscopic retrograde cholangiography can accurately define the level and cause of biliary obstruction; they are a first step in biliary drainage procedures and can accurately define biliary anatomy for the surgeon. These procedures increase intrabiliary pressure and can precipitate deterioration of a patient who is already septic. Accordingly, biliary drainage procedures should be anticipated.¹⁸ Magnetic resonance cholangiopancreatography is an important tool in diagnosis of obstructive biliary tract lesions.

Ultrasound

Real-time ultrasound can detect hepatic abscesses as small as 1.5 cm with a sensitivity of 75% to 90%. Pyogenic hepatic abscesses are extremely variable in shape and echogenicity. They are usually spherical (Fig. 88-2) or ovoid but may be lobulated or lentiform. Mural thickness is variable, and the wall typically is irregular and hypoechoic. On sonography, abscesses appear anechoic (50%), hyperechoic (25%), or hypoechoic (25%). Septa, fluid-fluid levels, internal debris, and posterior acoustic

Figure 88-1 *Escherichia coli* pyogenic liver abscess: pathologic findings. This 76-year-old woman died of sigmoid diverticulitis and pylephlebitis of the inferior mesenteric vein and portal vein, causing a liver abscess. **A.** Infected material is present within a portal vein (arrow). **B.** A multicompartmental suppurative liver abscess is present.

Figure 88-2 Pyogenic liver abscess: sonographic features. **A.** Transverse sonogram of the liver shows a complex, predominantly hypoechoic mass with posterior acoustic enhancement containing coarse, clumpy debris. **B.** Longitudinal sonogram of the liver in a different patient shows bright reflectors within the abscess due to gas.

enhancement may also be seen. Early lesions tend to be echogenic and poorly demarcated; they may evolve into well-demarcated, nearly anechoic lesions. If gas is present in an abscess, brightly echogenic reflectors with posterior reverberation artifact may be noted.¹⁹⁻²⁵

The sonographic differential diagnosis includes amebic or hydatid infection, necrotic or cystic neoplasm, hematoma, complicated biloma, and simple cyst with infection.

Nuclear Scintigraphy

Pyogenic liver abscesses appear as rounded, cold areas on technetium Tc 99m sulfur colloid and hepatobiliary scintiscans. On occasion, communication between the abscess cavity and the biliary system can be demonstrated on the ^{99m}Tc-sulfur colloid study.²⁶⁻²⁸

Gallium citrate Ga 67 scintigraphy and imaging with leukocytes labeled with indium In 111 are the two nuclear medicine techniques that were used for the detection of pyogenic abscess in the past but are abandoned today.

Magnetic Resonance Imaging

Hepatic abscesses, like most other focal hepatic processes, prolong T1 and T2 relaxation times.²⁹ At MRI, air within the abscess appears as a signal void and is therefore more difficult to differentiate from calcifications. However, the shape and location (air-fluid level) should enable the correct diagnosis. After administration of gadopentetate dimeglumine (Gd-DTPA), abscesses typically show rim enhancement (Fig. 88-3), which is secondary to increased capillary permeability in the surrounding liver parenchyma (the double target sign). Small lesions (<1 cm) may enhance homogeneously, mimicking hemangiomas.²⁹ Abscess wall enhancement on dynamic postgadolinium images may be considered a distinctive feature of pyogenic liver abscesses. Abscess wall shows a fast and intense enhancement that persists on portal venous and late-phase images. Some of the lesions may contain internal septations, which also reveal persistent enhancement on late-phase images.³⁰ Perilesional edema, shown as high signal on T2-weighted images, is associated with 50% of abscesses. However, it may also be seen in 20% to 30% of patients with

primary or secondary hepatic malignant neoplasms. Therefore, the presence of perilesional edema can be used only to differentiate a hepatic abscess from a benign cystic hepatic lesion.¹ Resolution of perilesional edema may indicate response to therapy.²⁹ Limitations of MRI in the investigation of patients with abscesses include the relatively high cost and the lack of easy access for drainage procedures.¹⁷

Computed Tomography

By virtue of its good spatial and contrast resolution, CT is the single best method for detecting hepatic abscess, with a sensitivity as high as 97% (Fig. 88-4). On CT scans, abscesses appear as generally rounded masses that are hypodense on both contrast and noncontrast scans. The attenuation ranges between 0 and 45 HU and thus overlaps with the appearance of cysts, bilomas, and hypodense neoplasms. Most have a peripheral rim or capsule that shows contrast enhancement in a pattern similar to that seen on MRI (see Fig. 88-2). Most abscesses are sharply defined, but a minority have a grossly lobular contour and circumferential “transition zones” of intermediate attenuation.^{24,31}

Another helpful finding is the transient segmental or wedge-shaped enhancement of the hepatic parenchyma surrounding an abscess on the arterial dominant phase of a contrast-enhanced dynamic CT scan.³²

Some abscesses show the cluster sign (see Fig. 88-4C-E), in which small, pyogenic abscesses appear to cluster or aggregate in a pattern suggesting coalescence into a single large cavity.

All of these findings are nonspecific and require aspiration for diagnosis. Central gas (see Fig. 88-4A), as either air bubbles or an air-fluid level, is a specific sign, but it is present in less than 20% of cases. A large air-fluid or fluid-debris level is often associated with communication with the gut.³³

TREATMENT

Effective treatment of pyogenic liver abscess entails elimination of both the abscess and its underlying source. Current therapeutic options include surgical drainage, antibiotics alone, percutaneous aspiration in conjunction with antibiotics, and percutaneous catheter drainage.^{2,5,34-49}

As a rule, aspiration alone is sufficient if the fluid collection is unilocular, well demarcated, and less than 5 cm in diameter and shows no communication with the gut or biliary tree. Unless the abscess is chronic and the cavity walls are fibrotic or calcified, small intrahepatic abscess cavities quickly collapse when aspirated, unlike abscesses in other organs and peritoneal spaces. In a retrospective study of 115 patients, excellent results were obtained with ultrasound-guided percutaneous needle aspiration of pyogenic abscesses followed by injection of antibiotics into the abscess cavity.⁴⁸ Cure was achieved in 98% of cases, with no deaths, complications, or recurrences at 3-year follow-up.⁴⁸ Fluid drainage usually requires introduction of a 16- or 18-gauge Teflon-sheathed needle into the collection and, if the fluid is extremely viscous, temporary insertion of a 5F to 8F pigtail catheter. All fluid is aspirated, and the cavity is irrigated with normal saline or an antiseptic solution.^{37,42}

Before removal of the catheter, the collection is injected with contrast medium to rule out communication with surrounding organs. Intravenous antibiotics are given before, during, and after the procedure and are changed accordingly when the infecting organism is identified.^{37,42}

Figure 88-3 Pyogenic liver abscess: MRI findings. Gadolinium-enhanced, fat-suppressed T1-weighted image shows a predominantly low signal intensity mass with enhancing wall and septations.

Figure 88-4 Pyogenic liver abscess: CT findings. **A.** Mottled gas collection is present in this right lobe abscess. **B.** A multifocal abscess is identified in this patient with cholangitis. Axial (**C**), coronal (**D**), and sagittal (**E**) images show the classic cluster sign of a multiloculated pyogenic liver abscess. Note the peripheral lobulations and thin enhancing wall.

An indwelling drainage catheter is usually required when the fluid collection is ill-defined, multiloculated, or more than 5 cm in diameter or when communication with the gut or biliary tree is suspected. A variety of drainage catheter styles (single lumen, double lumen, sump type) and sizes (8.3F–16F) are available.^{34,39} Most are made of a flexible Silastic material with a pigtail curve containing multiple side holes. Smaller catheters (8.3F–10F) are usually sufficient to adequately drain thin fluid collections or extremely small abscesses; large abscesses require larger catheters (12F–16F), especially if they contain particulate material. The catheter can be inserted under CT, ultrasound, or fluoroscopic guidance by the Seldinger or trocar technique. Other chapters contain complete discussions of imaging guidance and abscess catheterization. The catheter is left in place until drainage volume has decreased to less than 20 mL/day. If there is a known or suspected fistula, a fluoroscopic sinogram is obtained before catheter removal to rule out communication with bowel, bile duct, or pancreatic duct. If no fistula is present, most hepatic abscesses require only 2 to 14 days of drainage.^{37,42,49}

The failure and recurrence rates of catheter therapy are 8.4% and 8%, respectively. They are most often associated with complicated abscesses caused by fistula, phlegmons, or infected tumors.^{37,42,49}

Surgery is reserved for patients for whom percutaneous drainage has failed, those with associated intra-abdominal perforation of hepatic abscess, and those with fistula formation (e.g., biliary, colonic).

The mortality rate for pyogenic hepatic abscess has declined from 80% to less than 10% owing to earlier diagnosis, antibiotics, and advances in surgical and percutaneous drainage techniques.^{44,47}

Amebic Abscesses

INCIDENCE

Approximately 10% of the world's population is infected with *Entamoeba histolytica*, which causes more deaths than any other parasite with the exceptions of malaria-causing plasmodia and schistosomes. Less than 10% of infected individuals, however, are symptomatic. Amebic liver abscess is the most common extraintestinal manifestation, occurring in 3% to 7% of this population.^{50–56}

Although amebiasis is usually considered a disease of developing countries, certain groups are at high risk in Western nations: recent immigrants, institutionalized patients, and homosexual persons. Indeed, *E. histolytica* has been isolated in the stool of up to 30% of sexually active homosexual men; its clinical significance is unclear.⁵⁰ Worldwide, some 85% to 90% of amebic liver abscesses occur in men.

In the United States, the overall mortality rate for hepatic amebic abscess is 3%. It is less than 1% when the abscess is confined to the liver, 6% with extension into the chest, and 30% with extension into the pericardium.⁵⁷

PATHOGENESIS

The cystic form of *E. histolytica* gains access to the body by oral ingestion of infected material, usually contaminated water (Fig. 88-5A). The mature cysts are resistant to gastric acid and pass unchanged into the intestine. The cyst wall is then digested by trypsin; four invasive trophozoites are released, which live and multiply in the colon, particularly the cecum. The trophozoites exist in two forms, small (10-20 mm) and large (20-60 mm). The large form usually occurs in invasive amebiasis when the mucosa is invaded. This can cause minute superficial mucosal ulcerations. With further invasion, hemorrhage, perforation, enterocolic or cutaneous fistulas, amebic appendicitis, or ameboma formation can occur. Amebic trophozoites can also enter the mesenteric venules and lymphatics and be carried to the liver, lungs, and other organs. The liver can be invaded in one of three ways: through the portal vein (most common); through lymphatics; or by direct extension through the colon wall into the peritoneum and then through the liver capsule.^{2,4,52}

When a sufficient number of trophozoites become lodged in small hepatic venules, thrombosis and infarction of small areas of hepatic parenchyma occur (amebic hepatitis). The host's nutritional and immune status determine whether the initial infestation heals or progresses to a macroabscess. A visible abscess results from the coalition of multiple small areas of ischemic necrosis and amebic destruction of hepatic parenchymal cells.

Trophozoites that pass into the distal colon may change into round, resistant cysts (Fig. 88-5B) that pass into the feces. Indeed, human carriers who pass amebic cysts into their stool are the primary source of infection.^{2,4,54}

PATHOLOGY

The fluid of an amebic abscess is usually dark reddish brown and has the consistency of anchovy paste (Fig. 88-5C). This material is usually sterile, consisting of a mixture of blood and destroyed hepatocytes. Rarely, the trophozoites are found centrally within the paste, but they are often found in the zone of necrotic tissue adjacent to the outer abscess wall. The wall of connective tissue becomes better developed with age, and leukocyte infiltration and inflammatory reaction are characteristically absent. If the abscess is not treated, it may rupture into the peritoneum, pleural cavity, lung, or pericardium.^{2,4,54}

Amebic abscesses are most often solitary (85%) and affect the right lobe more often (72%) than the left lobe (13%). Solitary liver abscesses and right lobe predominance are more marked in amebic than in pyogenic abscesses because most infestations are transmitted through the portal vein. Amebiasis most often affects the right colon, which drains into the superior mesenteric vein, which preferentially streams into the right lobe. Flow from the inferior mesenteric vein (left colon) and splenic vein streams preferentially into the left lobe.^{2,4,54}

CLINICAL FINDINGS

Most patients with amebic liver abscess present with a tender liver and right upper quadrant pain. Compared with persons who have pyogenic liver abscess, they are more likely to have diarrhea and hepatomegaly and less likely to have jaundice or sepsis. Amebae are not found in the stool of most patients with an amebic liver abscess.⁵⁰⁻⁵²

Because clinical features and findings of stool examination for amebae usually are nonspecific or negative, serologic tests are particularly helpful when hepatic amebic abscess is suspected. The indirect hemagglutination test result is positive in more than 90% of these patients.⁵⁰⁻⁵²

RADIOLOGIC FINDINGS

Nuclear Scintigraphy

Amebic abscesses appear as cold defects on sulfur colloid scans. They often show "rim enhancement" on hepatobiliary scintiscans, presumably owing to inflammation of the adjacent parenchyma. A cold lesion with a hot periphery is suggestive of the diagnosis. Nevertheless, nuclear medicine techniques are not routinely used for detection of hepatic amebic abscess.

Ultrasound

Amebic abscess on ultrasound studies is usually a round or oval, sharply defined hypoechoic mass (Fig. 88-6) that abuts the liver capsule with homogeneous, fine, low-level echoes and distal acoustic enhancement.¹⁵ In comparison of amebic and pyogenic abscesses, amebic abscess is more likely to have a round or oval shape (82% vs. 60%) and a hypoechoic appearance with fine, low-level internal echoes at high gain settings (58% vs. 36%).^{20,58-63} On contrast-enhanced ultrasonography, pyogenic abscess appears as a partially enhancing lesion with a thin or thick rim of dense opacification and persistently hypoechoic center.⁶⁴

Computed Tomography

The CT appearance of amebic abscess is variable and nonspecific. The lesions are usually peripheral, round or oval areas of low attenuation (10-20 HU). A peripheral rim of slightly higher attenuation can be seen on noncontrast scans and shows marked enhancement after administration of contrast material (Fig. 88-7). A peripheral zone of edema around the abscess is also common and somewhat characteristic for this lesion.¹ Lesions may appear unilocular or multilocular and demonstrate nodularity of the margins. Concomitant extrahepatic abnormalities include right-sided pleural effusion, perihepatic fluid, and gastric or colonic involvement.^{65,66}

Magnetic Resonance Imaging

On MRI (Fig. 88-8), amebic liver abscesses are spherical and usually solitary lesions with a hyperintense center on T2-weighted images and a hypointense center on T1-weighted images. The abscess wall is thick, and on gadolinium-enhanced images, the enhancement pattern is similar to that of pyogenic abscess.^{1,30} Diffuse central inhomogeneity is often seen on T2-weighted images. Edema in otherwise normal surrounding parenchyma may be appreciated on T2-weighted images.^{67,68}

After treatment, abscesses become more homogeneously hypointense on T2-weighted images. Successful treatment may show concentric rings of different signal intensity surrounding the lesion on T2-weighted images.^{67,68}

COMPLICATIONS

Pleuropulmonary amebiasis is the most frequent complication of amebic liver abscess, occurring in 20% to 35% of patients. This may be manifested as pulmonary consolidation or abscess, serous effusion, empyema, or hepatobronchial fistula.^{50-52,69}

Figure 88-5 Amebiasis: pathologic findings. A. Life cycle. Cysts are passed in feces (1). Infection by *Entamoeba histolytica* occurs by ingestion of mature cysts (2) in fecally contaminated food, in water, or on hands. Excystation (3) occurs in the small intestine and trophozoites (4) are released, which migrate to the large intestine. The trophozoites multiply by binary fission and produce cysts (5), which are passed in the feces (1). Because of the protection conferred by their walls, the cysts can survive days to weeks in the external environment and are responsible for transmission. (Trophozoites can also be passed in diarrheal stools but are rapidly destroyed once outside the body and if ingested would not survive exposure to the gastric environment.) In many cases, the trophozoites remain confined to the intestinal lumen (A, noninvasive infection) of individuals who are asymptomatic carriers, passing cysts in their stool. In some patients, the trophozoites invade the intestinal mucosa (B, intestinal disease) or, through the bloodstream, extraintestinal sites such as the liver, brain, and lungs (C, extraintestinal disease), with resultant pathologic manifestations. It has been established that the invasive and noninvasive forms represent two separate species, respectively, *E. histolytica* and *E. dispar*; however, not all persons infected with *E. histolytica* will have invasive disease. These two species are morphologically indistinguishable. Transmission can also occur through fecal exposure during sexual contact (in which case not only cysts but also trophozoites could prove infective). **B.** Cyst of *E. histolytica*, permanent preparation stained with trichrome. **C.** Typical anchovy paste-like material drained from an amebic abscess. (A source: Centers for Disease Control and Prevention. <http://www.cdc.gov/parasites/amebiasis/biology.html>.)

Figure 88-6 Amebic abscess: sonographic features. A large, well-defined abscess is identified in the right lobe of the liver.

Figure 88-7 Amebic abscess: CT features. A large unilocular mass with an enhancing wall demonstrates a thin peripheral hypodense rim of surrounding edema that is typical of amebic abscesses.

Peritoneal amebiasis occurs in 2% to 7.5% of patients with amebic liver abscess. Sudden rupture is manifested dramatically, in the manner of a perforated viscus. Pericardial amebiasis is the most serious complication of amebic liver abscess because it can lead to progressive tamponade or sudden development of shock. Most abscesses responsible for this complication are located in the left hepatic lobe. Renal amebiasis is a rare complication that can result from abscess rupture.^{50-52,69,70}

TREATMENT

The complications of amebic liver abscess just mentioned are becoming less frequent because of earlier diagnosis, improved

imaging and serologic techniques, and effective medical, percutaneous, and surgical management.⁷¹ More than 90% of hepatic amebic abscesses respond to antimicrobial (metronidazole or chloroquine) therapy alone. The efficacy of these amebicidal agents has reduced the mortality rate of hepatic amebic abscesses from 81% to 4%.^{50-52,72,73}

There are, nevertheless, some circumstances in which aspiration and drainage of amebic abscess are indicated: to differentiate pyogenic from amebic abscess; for a large symptomatic abscess in which rupture is imminent; after poor response to medical therapy; with suspected bacterial superinfection; in pregnancy; for noncompliance with medical treatment; and as an alternative to surgery when an abscess ruptures. Drainage can be accompanied by intralesional delivery of drug, which can increase mean intralesional drug levels up to 246-fold.⁷⁴⁻⁷⁸

Confirmation of an amebic abscess may not always be possible by percutaneous aspiration. In one series, only 50% of patients had the classic “anchovy paste” appearance, and positive diagnoses based on fluid evaluation were established in only 5% of cases. Therefore, the primary role of percutaneous aspiration and drainage in these patients is the diagnosis and treatment of superimposed bacterial infection.⁷⁴⁻⁷⁸

Hepatic Echinococcal Disease

EPIDEMIOLOGY

Hydatid disease is prevalent throughout much of the world, and the two main forms that affect humans are *Echinococcus granulosus* and *Echinococcus multilocularis*. The disease flourishes in rural areas where dogs are used for herding livestock, especially sheep. Greece, Uruguay, Argentina, Australia, and New Zealand are the countries with the highest incidence of hydatid disease.⁷⁹

PATHOPHYSIOLOGY

E. granulosus is a small tapeworm, 3 to 6 mm long, that lives in the intestine of the definitive host, usually the dog. The life cycle (Fig. 88-9A) depends on a primary host harboring the adult worm and an intermediate (human) host harboring the larval stage. The adult parasite sheds eggs, which may infect humans when contaminated, unwashed vegetables are ingested or through contact with infected dogs, which may carry ova on their fur or shed them onto soil where children play.⁷⁹⁻⁸¹

In humans, the external shell of the egg is digested in the duodenum and the embryo is freed. The embryo actively penetrates the intestinal mucosa until it enters a blood vessel, from which it is transported until trapped by narrowing of the capillaries. Most are carried by the portal vein and trapped in the liver, but the lungs, spleen, kidneys, bone, and central nervous system can also be involved.⁷⁹⁻⁸¹

Although most embryos are destroyed by host defenses, surviving embryos (Fig. 88-9B) develop into the hydatid stage in 4 to 5 days while trapped within a capillary. After 3 months, this cyst measures 5 mm in diameter. The life cycle is complete when the infected intermediate host (sheep or other ruminant) dies and its viscera, which contain the larval form, are consumed by a definitive host.⁷⁹⁻⁸¹

E. multilocularis (*alveolaris*) is a less common but more aggressive form of echinococcus. The disease is endemic in central Europe, the former Soviet Union, Japan, and central

Figure 88-8 Amebic abscess: MRI features.

A. T2-weighted image shows the hyperintense center and the relatively less hyperintense abscess wall (arrow). **B.** Gadolinium-enhanced arterial phase T1-weighted image shows the hypointense center. In this phase, the wall does not enhance. Note the enhancing inflamed liver parenchyma surrounding the abscess (arrow). **C.** Portal venous phase image shows enhancement of abscess wall (arrow). (Courtesy Dr. N. Cem Balci, St. Louis University, St. Louis, MO.)

and northern North America.⁸²⁻⁸⁵ The main host of the adult parasite is the fox, although less commonly domestic dogs and cats may serve as hosts.⁸² The intermediate hosts, usually wild rodents, acquire infection by eating contaminated wild berries. Humans become infected either by eating wild fruits contaminated with fox feces or by direct contact with infected animals.⁸²⁻⁸⁴ The larvae reach the liver through the portal vein. Here they proliferate and penetrate surrounding tissue, which causes a diffuse and infiltrative process that simulates a malignant neoplasm. *E. multilocularis* organisms induce a brisk granulomatous reaction with central necrosis, cavitation, and calcification.⁷⁹⁻⁸¹

PATHOLOGY

The hydatid cyst has three layers composed of both host and parasite tissue (Fig. 88-9C). The outer pericyst is composed of modified host tissue that forms a rigid protective zone only several millimeters thick. As the cyst expands, the vessels and ductal structures of the liver become incorporated in the cyst wall; this explains enhancement of the wall on contrast CT and MR studies and angiography.

The two internal layers are formed by the parasite. The middle layer is a thicker (1-2 mm) laminated membrane that resembles the white of a hard-boiled egg and is easily ruptured with manipulation. It permits the passage of nutrients but is impervious to bacteria. Disruption of this layer predisposes to bacterial infection. The innermost or germinal layer (endocyst) is the living parasite, which is one cell thick. It produces the laminated membrane and scolices that represent the larval stage. Brood capsules are small spheres of disrupted germinal membrane that produce scolices (Fig. 88-9D). Free-floating

brood capsules and scolices form a white sediment of barely visible particles known as hydatid sand.

Cyst fluid is secreted by the germinal lining and normally is crystal clear. It is a transudate of serum that contains protein and is antigenic. The high secretion pressure is responsible for progressive cyst enlargement. Up to 60% of cysts are multiple.

In contrast to *E. granulosus*, the alveolar form has daughter cysts that arise on the outer surface of the original cyst with invasion of adjacent liver parenchyma.⁸⁶ On histologic examination, the cysts have a thick lamellated wall.^{86,87} Surrounding this is the marked granulomatous reaction with hepatic necrosis, collagenous tissue, multinucleated giant cells, and lymphocytes.⁷⁸ In contrast to the cysts of *E. granulosus*, the *E. alveolaris* cysts rarely contain scolices in human infestation.^{87,88}

CLINICAL FINDINGS

Most patients acquire hydatid disease in childhood but are not diagnosed until the third or fourth decade of life. Echinococcal cysts enlarge at a rate of approximately 1 cm/year. Most cysts are initially asymptomatic and remain so until they grow large enough to cause pain; erode into a moderate-sized bile duct, allowing cyst fluid to enter the bile (and vice versa), causing fever and jaundice; or induce an allergic reaction because of leakage of cyst fluid. Large cysts can obstruct blood and bile flow, leading to portal hypertension and jaundice.⁷²

Routine blood analysis is usually not helpful in establishing the diagnosis of hydatid disease. Results of serologic tests are positive in more than 80% of cases and are diagnostic of echinococcoses.⁷² The clinical manifestations of *E. multilocularis* may occur 5 to 20 years after the inciting event.⁸⁶⁻⁸⁸ Abdominal discomfort, jaundice, and hepatomegaly may be present, and

eosinophilia is frequently observed.^{86,89} Although the serum levels of the transaminases usually remain normal, alkaline phosphatase and γ -glutamyl transpeptidase values are elevated.^{86,88} Serologic titers are elevated in alveolar echinococcosis and aid in diagnosis.⁸⁹

RADIOLOGIC FINDINGS

Plain Radiographic Findings

Calcification is visible on 20% to 30% of abdominal plain radiographs (Fig. 88-10). The calcification is usually curvilinear or ringlike and lies in the pericyst. Daughter cysts may calcify, creating rings of calcification. Calcification does not always indicate death of the parasite, and small irregular areas of calcification may be secondary to dystrophic calcification in old blood clots.⁹⁰ *E. multilocularis* can cause faint or dense punctate calcification scattered throughout necrotic and granulomatous tissue.

Ultrasound

Hepatic hydatid disease is manifested sonographically in several different fashions (Fig. 88-11), depending on the stage of evolution and maturity: a well-defined anechoic cyst; an anechoic cyst except for hydatid sand; a multiseptate cyst with daughter cysts and echogenic material between the cysts (characteristic); a cyst with a floating, undulating membrane with a detached endocyst, the characteristic “water lily” sign; or a densely calcified mass. Daughter cysts usually cause mural thickening as well.^{15,91}

Ultrasound has been used to monitor the efficacy of medical antihydatid therapy. Findings suggesting a positive response include reduction in cyst size, membrane detachment, progressive increase in cyst echogenicity, and mural calcification.^{20,92-99} When hydatid cysts become infected, they lose their characteristic sonographic appearance and become diffusely hyperechoic.^{20,82,92-99}

Figure 88-9 Hydatid disease: pathologic findings. A. Life cycle. The adult *Echinococcus granulosus* (3-6 mm long) (1) resides in the small bowel of the definitive hosts, dogs or other canids. Gravid proglottids release eggs (2) that are passed in the feces. After ingestion by a suitable intermediate host (under natural conditions: sheep, goat, swine, cattle, horses, camel), the egg hatches in the small bowel and releases an oncosphere (3) that penetrates the intestinal wall and migrates through the circulatory system into various organs, especially the liver and lungs. In these organs, the oncosphere develops into a cyst (4) that enlarges gradually, producing protoscolices and daughter cysts that fill the cyst interior. The definitive host becomes infected by ingesting the cyst-containing organs of the infected intermediate host. After ingestion, the protoscolices (5) evaginate, attach to the intestinal mucosa (6), and develop into adult stages (1) in 32 to 80 days. The same life cycle occurs with *E. multilocularis* (1.2-3.7 mm), with the following differences: the definitive hosts are foxes and to a lesser extent dogs, cats, coyotes, and wolves; the intermediate hosts are small rodents; and larval growth (in the liver) remains indefinitely in the proliferative stage, resulting in invasion of the surrounding tissues. With *E. vogeli* (up to 5.6 mm long), the definitive hosts are bush dogs and dogs; the intermediate hosts are rodents; and the larval stage (in the liver, lungs, and other organs) develops both externally and internally, resulting in multiple vesicles. *E. oligarthrus* (up to 2.9 mm long) has a life cycle that involves wild felids as definitive hosts and rodents as intermediate hosts. Humans become infected by ingesting eggs (2), with resulting release of oncospheres (3) in the intestine and the development of cysts (4) in various organs.

Figure 88-9, cont'd B to D. Hydatid cysts are typically spherical and have the ability to achieve large sizes. The insides of the cysts are filled with fluid, brood capsules, daughter cysts, and protoscolices that have the capability to grow into adult worms if consumed by a definitive host. If a cyst is ruptured, which may occur through a sharp blow or during surgery, each protoscolex released may form a new cyst. Also, the fluid within the hydatids is highly allergenic and may cause anaphylactic shock and rapid death if it is freed inside the body. (A source: Centers for Disease Control and Prevention. <http://www.cdc.gov/parasites/echinococcosis/biology.html>.)

Figure 88-10 Hydatid cyst: plain radiographic findings. Curvilinear calcification of the pericyst is present in 20% to 30% of abdominal radiographs in patients with hydatid cysts.

E. multilocularis produces echogenic lesions that can be single or multiple and are usually situated in the right lobe.⁸² Irregular necrotic regions can be seen.^{82,100} Microcalcifications have been described in about 50% of cases.⁸² Intrahepatic biliary dilation is a common sonographic finding.⁸² *E. multilocularis* lesions are infiltrative with a propensity to spread to the liver hilum.⁸²

Computed Tomography

On CT scans, hydatid disease appears as unilocular or multilocular, well-defined cysts with either thick or thin walls.^{1,30} (Fig. 88-12). Daughter cysts are usually seen as areas of lower attenuation than the mother cyst and are usually oriented in the periphery of the lesion (see Fig. 88-12). Daughter cysts can also float free in the lumen of the mother cyst, so altering the patient's position may change the position of these cysts, confirming the diagnosis of echinococcal disease (Fig. 88-13). Curvilinear ringlike calcification is also a common feature.¹⁰¹⁻¹⁰⁷

E. multilocularis causes geographic, infiltrating lesions without sharp margins or high-attenuation rims. These low-density (14-40 HU) lesions are solid masses rather than cysts. There is little if any enhancement with intravenous administration of contrast material.⁸²⁻⁸⁸ These are invasive

Figure 88-11 Hydatid disease: sonographic features. **A.** Longitudinal scan shows a rounded, well-defined, multilocular hypoechoic lesion with echogenic internal septa due to *E. granulosus*. **B.** Hydatid cyst in the right lobe with wavy bands of delaminated endocyst (water lily sign, arrows). **C.** *E. multilocularis* cysts. Transverse ultrasound images obtained at different levels of the liver show *E. multilocularis* infection with the typical hailstorm pattern, characterized by multiple echogenic nodules with irregular and indistinct margins. (**B** and **C** from Mortelet, KJ, Segatto E, Ros PR: The infected liver: Radiologic-pathologic correlation. *RadioGraphics* 24:937-955, 2004.)

Figure 88-12 Hydatid disease: CT findings. **A.** CT scan shows a large multilocular cyst with a thick wall. Multiple daughter cysts line the periphery of the mass. **B.** Calcification is seen within the dominant cyst in the right lobe on this noncontrast scan. **C.** More caudal scan shows intrabiliary passage of hyperdense cyst contents (arrow). **D.** Contrast-enhanced scan at the same level as **C** demonstrates filling defects (arrow) within dilated intrahepatic bile duct. **E.** Precontrast scan in a patient with *E. alveolaris* demonstrates an extensive, infiltrative lesion with calcifications in the right lobe.

Figure 88-13 Hydatid disease: CT findings. Contrast-enhanced CT image of a patient with hydatid cyst (arrow).

rather than expansile lesions whose nonspecific appearance can simulate a primary or secondary hepatic tumor. Calcification, when it is present, is usually amorphous rather than ringlike. When the alveolar lesion is located centrally, it may cause hepatic lobar atrophy.⁸⁵

Magnetic Resonance Imaging

On MRI studies, the cyst component of echinococcal cysts is similar to that of other cysts, with long T1 and T2 relaxation

times (Fig. 88-14). However, because of its superb contrast resolution, MRI best demonstrates the pericyst, the matrix or hydatid sand (debris consisting of freed scolices), and the daughter cysts (Fig. 88-15).¹ The pericyst usually has low signal intensity on T1- and T2-weighted images because of its fibrous component. This rim and a multiloculated or multicystic appearance are distinctive features. The hydatid matrix appears hypointense on T1-weighted images and markedly hyperintense on T2-weighted images. When present, daughter cysts are hypointense relative to the matrix on both T1- and T2-weighted images.¹⁰⁸ Floating membranes have low signal intensities on T1- and T2-weighted images.

MRI with its multiplanar capabilities is useful in displaying extrahepatic extension of *E. multilocularis*, such as transdiaphragmatic spread to the pleura, lung, pericardium, and heart.^{83,109} The relationship between the hepatic lesions and vessels such as the hepatic veins and inferior vena cava is well delineated on MRI.⁸³ The regions of fibrous and parasitic tissue are of low signal intensity on T1- and T2-weighted sequences and correspond to areas of nonenhancement on CT scans.⁸³ Small cystic extensions from the main lesion are shown as peripheral areas of increased signal on T2-weighted images and are thought to represent the active portions of the disease.⁸³ Large regions of necrosis do not have a characteristic signal pattern.⁸³ Calcifications display low signal but are more difficult to identify on MRI than on CT.⁸³

COMPLICATIONS

Rupture, the major complication of echinococcal disease, can be classified into three types: contained, when only the endocyst

Figure 88-14 Hydatid disease: MRI features. **A.** Axial gradient-echo T1-weighted image shows a hydatid cyst with a hypointense fibrous pericyst (arrow). The hydatid matrix has intermediate signal intensity, and peripheral daughter cysts that are hypointense relative to the matrix are seen. **B.** On an axial T2-weighted image, the matrix is hyperintense and the daughter cysts again are relatively hypointense. (From Mortelet, KJ, Segatto E, Ros PR: *The infected liver: Radiologic-pathologic correlation*. *RadioGraphics* 24:937–955, 2004.)

ruptures and the cyst contents are confined by the host-derived pericyst; communicating, when cyst contents escape into biliary or bronchial radicles that are incorporated into the pericyst; and direct, when both the endocyst and pericyst tear, spilling cyst contents into the pleural, peritoneal, or pericardial cavity.¹¹⁰

When cyst contents enter the biliary tract (see Fig. 88-12B and C), the cyst becomes echogenic. Intrabiliary hydatid material, including echogenic or nonechogenic daughter cysts and echogenic fragmented membranes, may fill the biliary system. Cyst–bile duct communication may be manifested as interruption of the cyst wall adjacent to a bile duct wall. On CT scans, there is interruption of the cyst wall and higher attenuation hydatid material in the biliary system. On MRI studies, cyst rupture is recognized as an area of discontinuity of the low-intensity wall.^{111–116} A fat–fluid level within hepatic hydatid cysts has been described on CT and MRI studies of two patients with communicating rupture of the cysts into the biliary tree.¹¹⁷ Laboratory analysis of the contents of the hydatid cysts revealed elevated levels of bile, confirming that the fat seen in the cysts on CT and MRI scans represented lipid material within bile.¹¹⁷

This intrabiliary hydatid material can lead to obstructive jaundice. Passage of hydatid sand or hydatid liquid can also lead to inflammation and spasm of the sphincter of Oddi.^{118–121} Until surgery can be performed, endoscopic retrograde sphincterotomy can be used as a temporizing measure to decompress the obstructed biliary system. Some 25% of cysts become infected and are manifested clinically as abscess.

If *E. multilocularis* is left untreated, the outcome is invariably fatal within 10 to 15 years as the cyst continues to slowly grow and destroy hepatic tissue.^{84,86–93} In some cases with Budd-Chiari syndrome or inferior vena cava thrombosis, death may be sudden due to embolic events to the heart or pulmonary

arteries.⁸⁴ Another serious complication is hemorrhage from esophageal varices secondary to portal hypertension. Metastasis to the brain is a less common cause of death in patients with *E. multilocularis*.⁸⁹

TREATMENT

Hepatic hydatid cysts require drainage because medical therapy with mebendazole and albendazole is usually ineffective. There are two surgical approaches: radical, in which a pericystectomy and hepatic resection are performed; and conservative, with injection of scolicalid agents followed by evacuation of the cyst, removal of the germinal lining and laminated membrane, and closure, capitonnage, drainage, or omentoplasty of the remaining cyst cavity. Surgical complications are high, including a 4% mortality rate and a 50% complication rate. The recurrence rate is high for the conservative approach, and both procedures require approximately 3 weeks of hospitalization.^{122,123}

Hydatid disease of the liver has been treated percutaneously in an effort to obviate surgery and its attendant morbidity and mortality. At one time, percutaneous drainage or even diagnostic aspiration of these cysts was discouraged because of potential complications, such as anaphylactic shock and spread of daughter cysts into the peritoneum. This has not proved to be the case, particularly when a transhepatic approach is used. A new cutting device has been described that can percutaneously extract laminated membranes and all daughter cysts with little chance of fluid leakage.^{124–128} A single aspiration and drainage procedure with this instrument resulted in successful evacuation of cyst contents in 90% of patients, with few major complications and no recurrence.¹²⁹

Figure 88-15 Hydatid disease: MRI features. A patient with hydatid cyst. On the coronal (A) and axial (B) T2-weighted images, the lesion (arrow) appears hyperintense and includes daughter cysts. On the T1-weighted image (C), the lesion (arrow) is hypointense and does not show any enhancement after the injection of gadolinium (D). Note that the daughter cysts are darker (arrow) on the T1-weighted images.

A number of scolical agents have been used; hypertonic (20%) saline and alcohol are effective percutaneous therapies for hepatic hydatid cysts and are associated with low complication rates.^{130,131} Percutaneous therapy should be attempted only with an accessible, dominant cyst that is truly cystic and uncomplicated. Infected cysts and cysts that communicate with the biliary system require surgical drainage (Fig. 88-16).¹³²

The treatment of choice for patients with *E. multilocularis* is complete excision with partial hepatectomy where possible.^{83,84,88,89} In patients with extensive disease, palliative procedures including hepaticojejunostomy, portosystemic shunts, and drainage of necrotic areas or abscesses in combination with benzimidazole therapy may be undertaken to prolong survival.^{84,88} Prolonged mebendazole therapy may slow disease progression and suppress metastasis.⁸⁷⁻⁸⁹ More recent treatment strategies include hepatectomy with orthotopic liver transplantation to effect a cure.^{83,84,86} However, the disease can recur after liver transplantation.⁸⁶

Fasciola hepatica

Fasciola hepatica is a trematode liver fluke. Contaminated water or vegetables are causes of human infestations.¹³³ First, the metacercariae encyst in the stomach; by perforating the duodenal wall, they migrate into the peritoneal cavity; and after perforating the hepatic capsule, they reach the liver parenchyma, where they browse for approximately 6 weeks.¹³³ As soon as the parasites spread into the biliary system, they start to mature into adult parasites and begin to produce eggs. CT

Figure 88-16 Hydatid disease: CT findings. A large infected hydatid cyst (arrow) that shows an air-fluid level on the contrast-enhanced CT image.

is the best imaging modality to detect fascioliasis, which typically is manifested as multiple clustered hypoattenuating nodules and multiple branching, hypoattenuating subcapsular peripheral lesions pointing toward the hilum of the liver (Fig. 88-17).¹³³

Figure 88-17 Fasciola hepatica: MRI findings. A patient with *Fasciola hepatica* (arrow). Note the branching subcapsular peripheral lesions on T2-weighted (A) and portal venous phase (B) images.

Figure 88-18 Candidiasis: pathology. A. Gross specimen of the spleen shows multiple small, white nodules representing involvement by candidiasis throughout the parenchyma. B. Low-power photomicrograph shows multiple candidiasis microabscesses with a peripheral zone of fibrosis and a central area of necrosis (arrows). (From Mortelet, KJ, Segatto E, Ros PR: *The infected liver: Radiologic-pathologic correlation*. RadioGraphics 24:937–955, 2004.)

Figure 88-19 Candidiasis on CT and MRI. A. Contrast-enhanced CT scan of the liver shows multiple hypoattenuating microabscesses less than 1 cm in diameter disseminated throughout the hepatic parenchyma. B. Axial T1-weighted MR image reveals relatively hyperintense lesions less than 1 cm in diameter in the liver (arrows). (From Mortelet, KJ, Segatto E, Ros PR: *The infected liver: Radiologic-pathologic correlation*. RadioGraphics 24:937–955, 2004.)

Candidiasis and Fungal Infections

Candidiasis (Figs. 88-18 and 88-19) is the most frequently encountered systemic fungal infection in immunocompromised hosts. It is becoming more common with the acquired immunodeficiency syndrome (AIDS) epidemic and with

increasingly intensive chemotherapy. Indeed, hepatic candidiasis is found in 50% to 70% of patients with acute leukemia and 50% of those with lymphoma at the time of autopsy. Diagnosis is difficult on clinical grounds because blood cultures are positive in only 50% of affected patients, so cross-sectional imaging is necessary for diagnosis.¹³⁴⁻¹³⁶

On sonography, four major patterns of hepatic candidiasis are seen: wheel within a wheel, in which a peripheral zone surrounds an inner echogenic wheel, which in turn surrounds a central hypoechoic nidus that represents focal necrosis in which fungal elements are found early in the disease; bull's-eye, a 1- to 4-mm lesion with a hyperechoic center that surrounds a hypoechoic rim, present when the neutrophil count returns to normal; uniformly hypoechoic, the most common appearance attributable to progressive fibrosis; and echogenic, caused by scar formation.^{15,136-139} After antifungal therapy, the lesions increase in echogenicity and decrease in size, often disappearing altogether, although in some cases sonographic inhomogeneity of the liver may persist for up to 3 years after treatment.¹⁴⁰

On CT scans, the most common pattern is multiple small, rounded areas of decreased attenuation that may require both precontrast and postcontrast scans to be appreciated. Areas of scattered increased attenuation representing calcification can be seen on noncontrast scans. Periportal areas of increased attenuation, correlating with fibrosis, may be seen as well.¹⁴¹⁻¹⁴³

On the basis of available evidence, CT is more sensitive than ultrasound in detecting hepatic candidal lesions¹⁴⁴ (see Fig. 88-19). Although CT and ultrasound appearances may be suggestive of candidiasis, they are not specific, and a definitive diagnosis is necessary before treatment because antifungal drugs may have significant side effects. Percutaneous needle biopsy achieves a definitive diagnosis in the majority of cases.¹³⁴

On MRI, untreated nodules are minimally hypointense on T1-weighted pregadolinium and postgadolinium images and markedly hyperintense on T2-weighted images.¹ In the subacute presentation after treatment, lesions appear mildly to moderately hyperintense on T1- and T2-weighted images and also demonstrate enhancement after intravenous administration of contrast material. A dark ring is usually seen around these lesions with all sequences. Completely treated lesions are minimally hypointense on T1-weighted images, isointense to mildly hyperintense on T2-weighted images, and moderately hypointense on early postcontrast images. They become minimally hypointense in delayed phase images.^{145,146}

Candida microabscesses have been reported as cold lesions on both sulfur colloid and gallium scans.¹³⁸

Schistosomiasis

EPIDEMIOLOGY

Schistosomiasis is one of the most common and serious parasitic infections of humans. This disease affects 200 million people worldwide, and in endemic areas its prevalence is nearly 70%. Some 10% of patients in endemic areas develop hepatosplenic involvement. *Schistosoma japonicum* occurs in the coastal areas of China, Japan, Taiwan, and the Philippines. *Schistosoma mansoni* occurs in parts of Africa, in the Middle East and West Indies, and in the northern part of South America. *Schistosoma haematobium* is seen in North Africa, the Mediterranean, and southwest Asia.¹⁴⁷⁻¹⁴⁹

PATHOPHYSIOLOGY

The schistosomal larvae are shed by snails, the intermediate host, into fresh water (Fig. 88-20A). Human infection occurs

in the course of bathing in or wading through contaminated irrigation canals, streams, and ponds. The schistosomal cercariae penetrate intact skin or mucous membranes and then migrate through venules and lymphatics to the heart. They pass through the pulmonary circulation to enter the mesenteric circulation. All schistosomes die except those that enter the mesenteric arteries, where they pass through capillaries into the portal venous system and mature within intrahepatic portal venous radicles. The host responds to the ova with granulomatous inflammation, which becomes replaced by fibrous tissue, leading to periportal fibrosis. If the trematode infestation is sufficiently chronic and heavy, progressive intrahepatic portal vein occlusion, presinusoidal portal hypertension, varices, and splenomegaly result. Schistosomiasis is the most common cause of portal hypertension worldwide. These parasites (Fig. 88-20B) are also known as blood flukes, and the importance of their vascular location cannot be overemphasized.²¹

The life cycle is completed when the mature female worm, after living within the male in the portal vein for some 10 to 15 years, swims against blood flow to reach the venules of the urinary bladder (*S. haematobium*) or gut (*S. mansoni*, *S. japonicum*) to deposit eggs. The eggs pass through the wall of the intestine or bladder to release miracidia, which infect mollusks. Cercariae emerge after maturing in their intermediate host.

PATHOLOGY

In severe *S. mansoni* and *S. japonicum* infections, the liver is dark colored, showing a bumpy but not nodular surface that is distinct from the appearance of ordinary cirrhosis. Cut section reveals granulomas (Fig. 88-20C) with widespread periportal fibrosis beginning in the porta hepatis and extending peripherally. The intervening parenchyma, however, is not distorted by regenerative nodules. The fibrous triads simulate the cross section of a clay pipe stem. Some portal triads lack a perceptible vein, and latex casts demonstrate widespread distortion and blockage of the portal vascular bed. These features account for the portal hypertension. Jaundice and hepatocellular necrosis usually ensue after variceal hemorrhage.^{146,148}

CLINICAL FINDINGS

Schistosomiasis is an insidious and chronic disease. Because hepatocellular necrosis occurs late in its course, patients may seek medical attention for portal hypertension and variceal bleeding. Patients with *S. haematobium* infection, which affects the liver less severely, typically present with hematuria resulting from urinary tract involvement.²¹

RADIOLOGIC FINDINGS

Conventional Studies

Calcification is usually too faint to be appreciated on abdominal plain radiographs. Splenomegaly is commonly seen, and barium studies may reveal esophageal and gastric varices.

Ultrasound

In patients with severe hepatic disease, thick, densely echogenic bands replace the portal triads. They sometimes reach a

Figure 88-20 Schistosomiasis: pathologic findings. A. Life cycle. Eggs are eliminated with feces or urine (1). Under optimal conditions, the eggs hatch and release miracidia (2), which swim and penetrate specific snail intermediate hosts (3). The stages in the snail include two generations of sporocysts (4) and the production of cercariae (5). On release from the snail, the infective cercariae swim, penetrate the skin of the human host (6), and shed their forked tail, becoming schistosomula (7). The schistosomula migrate through several tissues and stages to their residence in the veins (8, 9). Adult worms in humans reside in the mesenteric venules in various locations, which at times seem to be specific for each species (10). For instance, *S. japonicum* is more frequently found in the superior mesenteric veins draining the small intestine (A), and *S. mansoni* occurs more often in the superior mesenteric veins draining the large intestine (B). However, both species can occupy either location, and they are capable of moving between sites, so it is not possible to state unequivocally that one species occurs only in one location. *S. haematobium* most often occurs in the venous plexus of bladder (C), but it can also be found in the rectal venules. The females (7–20 mm; males slightly smaller) deposit eggs in the small venules of the portal and perivesical systems. The eggs are moved progressively toward the lumen of the intestine (*S. mansoni* and *S. japonicum*) and of the bladder and ureters (*S. haematobium*) and are eliminated with feces or urine, respectively (1). Pathology of *S. mansoni* and *S. japonicum* schistosomiasis includes Katayama fever, presinusoidal egg granulomas, Symmers pipestem periportal fibrosis, portal hypertension, and occasional embolic egg granulomas in brain or spinal cord. Pathology of *S. haematobium* schistosomiasis includes hematuria, scarring, calcification, squamous cell carcinoma, and occasional embolic egg granulomas in brain or spinal cord. **B.** *S. mansoni* egg (iodine stain). **C.** Low-power photomicrograph of a liver specimen reveals calcified eggs (arrows) and fibrosis in the subcapsular region. (A source: Centers for Disease Control and Prevention. <http://www.cdc.org/pdfs/schistosomiasis/biology.html>. C from Morteale, KJ, Segatto E, Ros PR: The infected liver: Radiologic-pathologic correlation. RadioGraphics 24:937–955, 2004.)

Figure 88-21 Schistosomiasis on CT and ultrasound. Hepatic *Schistosoma japonicum* infection. **A.** Sonogram demonstrates thick and densely echogenic bands producing a network pattern. **B.** Contrast-enhanced CT scan demonstrates capsular calcification (arrow) and gross septations (arrowheads).

thickness of 2 cm, radiating from the porta hepatis to the periphery. When scanning is performed perpendicular to the triad, rounded foci of echogenic material with a hypoechoic rim can be identified. This produces a “network” pattern with echogenic septa outlining polygonal areas of relatively normal liver (Fig. 88-21A).¹⁵⁰ A “bird’s claw” appearance is present at bifurcating points. Early, the liver is enlarged, but as periportal fibrosis progresses, it becomes contracted and the features of portal hypertension (varices, splenomegaly, ascites) become more apparent.¹⁵¹

Computed Tomography

Peripheral hepatic or capsular calcification is the hallmark of *S. japonicum* infection (Fig. 88-21B). The liver also shows gross septations that contain numerous calcified *Schistosoma* eggs resulting in bands of calcification described as a “turtle back” appearance.^{152,153} Prominent periportal low-density areas may also be present. There is an increased incidence of hepatocellular carcinoma in these livers.¹⁵³ In patients with acute schistosomiasis (Katayama syndrome), multiple hypodense nodules may develop.¹⁵³

S. mansoni infection is manifested as low-density, rounded foci with linear branching bands that encompass the portal tracts. These fibrotic bands sometimes show enhancement with contrast material but usually do not calcify.^{137,150}

Magnetic Resonance Imaging

On MRI, the septa are of low signal on T1-weighted scans and are hyperdense on T2-weighted images and reveal enhancement on postgadolinium images.³⁰ The septal calcifications are depicted less well on MRI than on CT.^{150,154}

Angiography

Angiography shows the hemodynamic changes of presinusoidal portal hypertension: normal hepatic venous outflow, decreased portal blood flow, and compensatory increased hepatic arterial flow. Wedged hepatic venous pressure is normal or only slightly elevated compared with portal hypertension resulting from alcoholic cirrhosis.

TREATMENT

Praziquantel, an isoquinoline derivative, and oxamniquine are effective against schistosomal infestation. Colchicine, an antiparasitic agent, has shown encouraging results in the treatment of schistosome-induced hepatic fibrosis.²

Pneumocystis carinii (*Pneumocystis jiroveci*) Infection

Pneumocystis carinii (*P. jiroveci*) is the most common cause of opportunistic infection in patients with AIDS. Nearly 80% of AIDS patients are affected, and extrapulmonary dissemination is becoming increasingly common.^{21,155}

P. jiroveci infection of the liver can be manifested sonographically as diffuse, tiny, nonshadowing echogenic foci or extensive replacement of normal liver parenchyma by echogenic clumps of dense calcification. This pattern, although suggestive, has also been reported in *Mycobacterium avium-intracellulare* and cytomegalovirus infection.¹⁵⁶ On CT scans, these regions are first hypodense but then become characteristically calcified. The calcifications may be punctate, nodular, or rimlike.¹⁵⁷⁻¹⁵⁹

Tuberculosis

Tuberculosis is an infectious disease in which different ways of liver involvement may be seen. Being one of the most common infectious diseases, tuberculosis has two forms of presentation, miliary and local. The local form has two subdivisions as nodular tuberculosis (tuberculoma or abscess) and hepatobiliary tuberculosis.^{1,160,161} Imaging techniques are most frequently not adequate to detect miliary tuberculosis, in which hepatomegaly is usually the only radiologic finding. Tuberculomas may be manifested as hypoechoic round masses at ultrasound, nonenhancing hypodense lesions at CT, and hypointense lesions on T1-weighted images and hypointense to isointense lesions on T2-weighted images at MRI.¹⁶¹

The liver has quite accurately been called the custodian of the *milieu intérieur*, and as such, it is vulnerable to a variety of metabolic, vascular, toxic, infectious, and neoplastic insults. Diffuse liver disease can be diagnostically challenging because of nonspecific and overlapping clinical signs and symptoms or even asymptomatic disease. The ability to assess liver and spleen size and the presence of ascites is limited on physical examination. Liver function tests also lack diagnostic specificity, are affected by nonhepatic factors, and in general poorly correlate with physiologic hepatic function.¹⁻⁴

Imaging plays a critical role in the diagnosis and treatment of diffuse liver disease by detecting its presence, determining its distribution and severity, and identifying associated complications, such as cirrhosis, portal hypertension, and malignant disease. Dramatic advances, particularly in magnetic

resonance imaging (MRI), have led to novel techniques to noninvasively diagnose and to characterize patterns of diffuse hepatic disease.

Hepatic Steatosis

The excessive accumulation of intracellular fat within hepatocytes, known as hepatic steatosis, occurs as a metabolic complication of a variety of hepatic exposures (Table 89-1). Common causes include alcohol abuse and viral hepatitis (discussed separately), obesity and metabolic disorders, toxins, human immunodeficiency virus (HIV) infection, genetic lipodystrophies, and chemotherapy. This abnormal intracellular accumulation of fat within hepatocytes is now recognized as an important causative factor in liver injury. Although it is initially reversible,

TABLE 89-1 Causes of Hepatic Steatosis

Trauma

the process may also progress and can result in cirrhosis and increased risk for hepatocellular carcinoma (HCC).⁵⁻¹⁰

Nonalcoholic fatty liver disease (NAFLD) is a disease spectrum extending from simple steatosis to the more severe form with inflammation and fibrosis known as nonalcoholic steatohepatitis (NASH), the result of hepatic metabolic disturbance in the absence of alcohol abuse. Steatosis is the hallmark feature of NAFLD. NASH is established histopathologically by the presence of steatosis with evidence of hepatitis (centrilobular inflammation, hepatocyte ballooning degeneration, and spotty necrosis) and variable degrees of fibrosis (stages 0-3). Advanced or stage 4 fibrosis is indicative of cirrhosis. Severity of NASH is based on grading of inflammation and different stages of fibrosis.¹¹ As a result of the current epidemic of obesity and metabolic syndrome, NAFLD is reported to occur in 20 to 80 million Americans and is the most common chronic liver disease in the United States. Recent research suggests that NAFLD is an independent risk factor for cardiovascular disease and contributes to the development of diabetes by impairment of insulin regulation within the liver.¹²⁻¹⁴

The development of HCC is common in steatohepatitis; up to 7% of patients with NAFLD-related cirrhosis develop HCC within 10 years. The population of patients with chronic liver disease is growing, particularly from NAFLD, and it is anticipated to become an increasingly significant burden on the health care system as well as the number one cause of cirrhosis and HCC.⁹

CLINICAL FINDINGS

Hepatic steatosis from any cause is often clinically asymptomatic, which clinically increases the challenge for early

intervention and treatment of the patient. In NAFLD, liver chemistry values are often normal. On physical examination, liver size may be normal or slightly enlarged and potentially difficult to evaluate in the obese patient. Alcohol-related steatosis can be manifested with vague right upper quadrant pain, with or without hepatomegaly, and is more often associated with liver function test abnormalities. One third of patients with alcoholism, however, have a fatty liver and are asymptomatic. Hepatic steatosis is also commonly seen in oncology patients as a result of chemotherapy administration, and its presence can impair imaging detection of concurrent metastatic disease. Hepatic steatosis with concomitant viral hepatitis can accelerate cellular damage and also decreases the effectiveness of antiviral therapies. Less commonly, hepatic steatosis can develop acutely secondary to pregnancy, carbon tetrachloride exposure, or binge drinking and can be manifested with jaundice, acute hepatic failure, or encephalopathy.^{2,6,15}

Hepatic steatosis is a potentially reversible disease treatable by removal of the insulting agent such as alcohol, other drug cessation, or treatment of infection. NAFLD can be treated by weight loss; however, it is often difficult for patients to achieve the recommended amount (5%-10% of body weight)¹⁶ without intervention, such as gastric bypass or banding surgery.^{17,18} Bariatric surgery patients have an incidental rate of 91% with NAFLD and 37% with steatohepatitis.¹⁹ Cellular damage from inflammation and the development of fibrosis and cirrhosis are irreversible, however, and the definitive treatment to prevent liver failure is transplantation. The early reversibility of this disease obviates the need for effective screening and treatment in a largely asymptomatic population.

PATHOLOGIC FINDINGS

Fat is deposited in the liver as a result of a number of metabolic derangements. These include increased hepatic synthesis of fatty acids (alcohol), decreased hepatic oxidation or utilization of fatty acids (carbon tetrachloride, high-dose tetracycline), impaired release of hepatic lipoproteins, and excessive mobilization of fatty acids from adipose tissue (starvation, steroids, alcohol).^{2,20,21}

On pathologic examination, lipid accumulates within the cytoplasm of the hepatocyte, predominantly in the centrilobular zone (Fig. 89-1). As lipid accumulation progresses, these small vacuoles coalesce, creating large, clear, macrovesicular spaces that peripherally displace the cell nucleus and virtually transform the hepatocyte into a lipocyte. Retention of water and protein adds to cellular enlargement. The liver may weigh 4 to 6 kg (normal, 1.5-2.5 kg) and at gross pathologic examination has a soft, yellow, greasy cut surface.²²

Segmental areas of fatty infiltration of the liver may develop as a result of a variety of traumatic and ischemic insults that reduce the amount of nutrients and insulin normally necessary to produce glycogen, culminating in a “metabolic infarct” of the involved region. Fatty replacement occurs where glycogen is depleted from the liver. This occurs primarily in regions where portal venous blood is reduced secondary to tumor, Budd-Chiari syndrome, or vascular thrombus. There is a difference in hormonal balance between the right and left lobes; pancreatic and splenic venous blood contains higher concentrations of insulin, and glycogen preferentially supplies the left portal vein.^{2,21,22} Accordingly, fat often infiltrates the right lobe of the liver before involvement of the left.

Figure 89-1 Hepatic steatosis: pathologic findings. **A.** Gross specimen shows a yellow, greasy liver that has undergone diffuse fatty metamorphosis. **B.** Pathologic specimen shows lipid accumulation within the hepatocytes, primarily in the centrilobular zone.

Focal fat sparing of the parenchyma in an otherwise fatty liver can also present as a diagnostic challenge. This occurs in characteristic locations, including the inferior medial portion of the liver, along the gallbladder fossa adjacent to the interlobar fissure, subcapsular portions of the liver, and adjacent to the porta hepatis. Direct vascular communications to the portal system from aberrant gastric venous flow or accessory cystic veins are found in certain areas of these spared regions, and it is postulated that these areas are perfused by systemic blood rather than by splanchnic venous blood from the portal veins. The posterior aspect of segment IV, a common area to be spared in diffuse fatty infiltration, has been shown to have aberrant direct gastric venous flow when focal fat sparing is present. Consequently, a “third blood supply” to these areas may help spare them the adverse effects of toxic agents entering through the portal circulation.^{23,24}

RADIOLOGIC FINDINGS

Several major patterns of fat deposition can be visualized at cross-sectional imaging: diffuse deposition; focal deposition and focal sparing; multifocal deposition; perivascular deposition; and subcapsular deposition.²⁵ Diffuse deposition is the most common pattern and is associated with homogeneous involvement and hepatomegaly. Focal deposition or diffuse deposition with focal sparing is a less common pattern that characteristically occurs adjacent to the falciform ligament, fissure for the ligamentum venosum, porta hepatis, and gallbladder fossa. This probably relates to variant arterial supply or venous drainage as described before. A true mass can be differentiated from focal regions of fat deposition and focal sparing because these occur in characteristic locations and typically have a geographic shape (but may appear nodular), poorly delineated margins, and, importantly, absence of mass effect on blood vessels.²⁵ Multifocal deposition of fat may simulate true masses such as metastases. In these patients, differentiation can be made by measurement of the tissue density on computed tomography (CT) or specific sequences performed with MRI to evaluate for the presence of fat. With perivascular fat deposition, halos of fat surround the hepatic or portal veins. This fat is tramlike or tubular in appearance when the course is in the imaging plane and ringlike or round for vessels with a course perpendicular to the imaging plane.²⁵ Subcapsular fat deposition can be seen in patients with renal failure and insulin-dependent diabetes in which insulin is added to the peritoneal

dialysate. The dialysate exposes the subcapsular hepatocytes to a higher concentration of insulin than in the remainder of the liver and promotes the esterification of free fatty acids into triglycerides. This in turn results in subcapsular deposition of fat.²⁵

Plain Radiographs

Plain film radiography is relatively insensitive to the presence of fat in the liver unless marked degrees of infiltration are present. In these cases, the liver may appear hyperlucent and blend imperceptibly with the right retroperitoneal fat stripe. This produces a visible interface between the combined radiolucency of the fatty liver and flank stripe and the relatively radiodense abdominal musculature. A fat-fluid interface may be present if the patient has ascites. The outer wall of the gut may produce a viscus wall sign as the soft tissue density of the bowel wall is contrasted with the fatty liver. These changes, however, are most commonly seen in pediatric patients.

Ultrasound

Ultrasound is the most common modality used to evaluate the liver and is often the first imaging examination performed. It is low in cost, fast, and readily available. The positive predictive value for the presence of steatosis is low, however, at 62% to 77%.^{26,27} It is also operator dependent and difficult in obese patients, who represent a large population of those patients requiring assessment.

On sonographic evaluation, in diffuse hepatic steatosis, there is increased hepatic echogenicity roughly proportional to the histopathologic grade of steatosis²⁸⁻³¹ (Fig. 89-2). Sonographic changes also tend to correlate with the severity of biochemical and clinical dysfunction. The key ultrasound findings are accentuation of the brightness of parenchymal echoes and an increased number of echogenic foci resulting from the proliferation of fat-nonfat interfaces. These small echogenic foci increase attenuation of the ultrasound beam, resulting in poor visualization of deep hepatic structures and of the hepatic venous system.

Normally, four to six portal and hepatic veins are seen per longitudinal section of the right lobe. With fatty infiltration, fewer vessels are seen, and the smaller vascular structures may be nonvisible. This dropout of vessels is due to physical vascular compression by parenchymal swelling, decreased sound penetration, and loss of contrast between echogenic vascular walls

Figure 89-2 Hepatic steatosis: spectrum of sonographic findings. **A.** Linear array high-frequency transducer shows an echogenic liver with a smooth capsule (arrows) in a patient with nonalcoholic steatohepatitis. **B.** This is in marked contrast to the nodular surface (arrows) of the liver in this patient with posthepatitis cirrhosis. **C.** Sagittal scan of the right lobe of the liver shows an enlarged, echogenic liver with poor sound penetration. The walls of the hepatic veins and portal veins are not defined. **D.** Oblique scan shows geographic steatosis in the anterior aspect of the liver, with focal sparing posteriorly. Note the sharp delineation (arrows) between the involved portions of liver. **E.** Focal fatty deposition is identified in the right lobe of the liver, adjacent to the interlobular fissure (arrow). (*D* courtesy of Peter Cooperberg, MD, Vancouver, British Columbia, Canada.)

and abnormally increased echogenicity of the surrounding parenchyma.²⁸⁻³⁰

Four sonographic patterns of focal fatty infiltration have been described: (1) hyperechoic nodule, (2) multiple confluent hyperechoic lesions, (3) hypoechoic skip nodules, and (4) irregular hyperechoic and hypoechoic areas. On occasion, a focal area of liver parenchyma may be spared from fatty metamorphosis and appear as an ovoid, spherical, or sheetlike hypoechoic mass in an otherwise echogenic liver. The characteristic

location, lack of mass effect on surrounding vessels, straight linear interface between normal and fatty parenchyma, and increased echogenicity of the liver compared with the cortex of the right kidney are useful diagnostic criteria. Hepatic hemangiomas, most often sonographically hyperechoic, in the presence of fat may appear hypoechoic compared with the adjacent liver and simulate a suspicious mass. Focal fatty infiltration in an otherwise normal-appearing liver may also produce a hyperechoic space-occupying mass. An angular or interdigitating

geometric margin, when present, is characteristic of focal fat.²⁸⁻³¹ Hepatic steatosis and fibrosis appear similar on ultrasound and often coexist. Differentiation of hepatic steatosis from a mass or other liver pathologic process may necessitate confirmation with CT or MRI, both of which have an increased sensitivity.

Technical considerations are important in the sonographic diagnosis of focal fat. The operator should take care not to erroneously change the time-gain-compensation curve, which can cause fatty parenchyma to have normal rather than increased echogenicity, whereas the spared, normal liver appears abnormally hypoechoic, simulating focal disease.

Computed Tomography

CT is an imaging technique that is also fast and widely available (Fig. 89-3). It is a strong diagnostic tool for hepatic steatosis because of the excellent correlation between the hepatic parenchymal CT attenuation value and the amount of hepatic triglycerides found on liver biopsy specimens.^{23,24}

On non-contrast-enhanced scans, the normal liver appears homogeneous with an attenuation value ranging from 50 to 70 Hounsfield units (HU), which is 8 to 10 HU greater than the attenuation of the spleen.^{23,24} The diffusely steatotic liver has a reduced attenuation value of less than 40 HU and appears and measures less dense than the spleen. The accumulation of other substances, such as iron, copper, glycogen, drugs (including amiodarone and gold therapy), and even cirrhosis or edema, can increase the attenuation value of the liver and underestimate the presence of fat. CT is also insensitive for mild steatosis, which makes it a poor screening tool for early disease. In a study of potential liver donors, unenhanced CT was able to provide an accurate diagnosis of macrovesicular steatosis of 30% or greater.^{23,24} A meta-analysis from 2011 compared CT with histopathologic examination with an overall sensitivity of 46.1% to 77%.³²

The rapid intravenous administration of contrast medium causes transiently increased attenuation of the spleen in comparison with the liver secondary to differences in vascularity that vary with rate of contrast agent administration and scan acquisition time, particularly early (<100 seconds) after the infusion, which can mimic the presence of fat in a normal liver.³³ Hepatic steatosis can be suggested on postcontrast images, with confirmation needed, preferably, on noncontrast or delayed phase postcontrast imaging. A recent publication on assessment of hepatic steatosis with contrast-enhanced CT found this technique 100% specific but only 60.5% sensitive.³³

In patients with NASH, the mean liver-to-spleen attenuation ratio is 0.66.^{23,24} The craniocaudal span of the liver has a mean of 21.4 cm; hepatomegaly is present in 92% of patients.^{23,24} The caudate lobe-to-left lobe ratio is usually normal (mean, 0.43), as is the preportal space (mean, 4.5 mm). Mildly prominent lymph nodes are present in the porta hepatis in 58.3% of patients. In mild but visible steatosis, the diagnosis can be made by comparing the relative CT attenuation of the liver and spleen, which appear and measure nearly equal. In more severe steatosis, the liver appears less dense than the spleen as well as the portal and hepatic veins, simulating the appearance of intravascular contrast material on a noncontrast examination.^{23,24}

Hepatic steatosis is manifested with a wide spectrum of CT appearances (see Fig. 89-3). Although diffuse parenchymal involvement is commonly seen, similar to the ultrasound appearance, fat may also be deposited in a focal, lobar,

segmental, or nonpattern-like distribution. Fatty infiltration of the liver can obscure the detection of focal liver lesions, such as neoplasm or abscess, by lowering the background liver attenuation to a level similar to that of an otherwise hypoattenuating mass or fluid collection.

When fatty infiltration is lobar, segmental, or wedge shaped, differentiation from other focal hepatic disease is straightforward. In such cases, it usually has a straight-line margin, typically extending to the liver capsule without associated bulging of the contour to suggest an underlying mass. When the steatosis is focal or nodular, differentiation from metastatic disease can be challenging. Absolute attenuation values are affected by multiple parameters other than fat as previously described and alone are not diagnostically reliable. The previously mentioned differentiating features of focal fat, including characteristic location, lack of contour abnormality, and normal course of the hepatic vessels, are helpful and are only rarely simulated in metastatic tumor lesions. On occasion, discrete focal areas of fatty replacement have a central core of normal-appearing tissue, the reverse of the typical tumor necrosis pattern.^{23,24}

Because of its unique ability to characterize the presence of fat, MRI is often required. It is the most reliable diagnostic tool in differentiating any geographic pattern of hepatic steatosis or fatty sparing from metastatic disease.³⁴

Magnetic Resonance Imaging

MRI is the most sensitive modality for hepatic steatosis and has the highest correlation with histopathologic evaluation with a sensitivity of 76.1% to 95.3%.³² In addition, MRI can be used to quantify the amount of fat present. Severity of liver fat or steatosis is categorized by a 4-point grading system for histopathologic liver fat of 0 to 3, representing less than 5%, 6% to 33%, 34% to 66%, and more than 66%, respectively.³⁵ The grading system incorporates the accepted normal value of liver fat, which is less than 5%. Limitations of MRI include increased cost, longer time to be performed, and less widespread availability. MRI also requires the patient's cooperation, such as the ability to lie still and breath-hold.

Proton chemical shift imaging, also termed opposed-phase gradient-echo imaging, is a rapidly acquired, high-resolution, and commonly used sequence to confirm the presence of microscopic fat within multiple organs including the liver, kidney, and adrenal gland (Fig. 89-4A, B). This technique capitalizes on the difference in precession frequency between fat and water protons (3.7 ppm). Imaging is performed when their signals are additive (in-phase) and opposite or subtractive (opposed-phase). The presence of water alone in a solid organ will have the same signal intensity on both the in-phase and opposed-phase images. When fat and water are present, signal will be lost in the corresponding area on the opposed-phase image only because of cancellation of the contribution of signal from both water and fat in opposite phases or direction.³⁶ At 1.5T, water and fat are in-phase every 4.6 ms (2.3 ms at 3T), with signal acquired at 4.6 ms, 9.2 ms, 13.4 ms, and so on (2.3 ms, 4.6 ms, 6.9 ms, and so on at 3T). Opposed-phase imaging occurs at 2.3 ms and every subsequent interval of 4.6 ms (6.9 ms, 11.5 ms, and so on). At 3T, opposed-phase imaging starts at 1.15 ms and is performed at every multiple of 2.3 ms (3.5 ms, 5.8 ms, and so on). A fat signal fraction can be calculated to quantify fat by the equation $(IP - OP)/(2IP)$, where IP is the signal of the liver with in-phase divided by the signal of the spleen with in-phase and OP is the signal of the

Figure 89-3 Hepatic steatosis: spectrum of CT findings. **A.** Diffuse hepatic steatosis. The density of the liver parenchyma is lower than that of the spleen on this unenhanced CT scan. Note how the intrahepatic blood vessels stand out as hyperattenuating structures. **B.** CT scan shows several hypodense masses in a patient with colon cancer. In-phase (**C**) and opposed-phase (**D**) MR images show that these hypodense areas represent fat. **E.** Perivascular steatosis in a patient with cystic fibrosis. Notice the fat highlighting the hepatic blood vessels. **F.** Capsular steatosis (arrows) is identified in this diabetic patient with renal failure and peritoneal dialysis who had received insulin in the dialysis fluid. Figure 89-4 Hepatic steatosis: spectrum of MR findings. **A.** In-phase T1-weighted spoiled gradient-echo image demonstrates normal hepatic signal intensity. **B.** Opposed-phase image shows diffuse loss of hepatic signal intensity indicating diffuse hepatic steatosis. Note the focal region of sparing (arrow) adjacent to the falciform ligament in the medial segment of the left hepatic lobe. **C** and **D.** Color maps of the liver show signal intensity loss in a healthy subject corresponding with grade 0 steatosis (**C**) and in a subject with grade 3 steatosis (**D**). **E.** Corresponding color scale for signal intensity loss by steatosis grade.

liver with opposed-phase divided by the signal of the spleen with opposed-phase. Inclusion of the spleen signal is used to normalize inherent imaging inhomogeneities. In normal liver, the lipid fraction is less than 10% and is without significant signal loss on opposed-phase imaging. Clinically significant hepatic steatosis is often greater than 20%³⁷ and can be detected with proton chemical shift imaging qualitatively with a visualized signal loss or quantitatively by creation of a fat signal fraction map (Fig. 89-4C-E). Chemical shift imaging is limited in the detection of a low amount of fat (<10%); at higher levels, fat amount is detected but ambiguous, with 40% fat appearing the same as 60%, reducing accurate quantification at these levels. Additional methods to detect fat include fat suppression with either T1 or T2, which performs as well as or better than chemical shift imaging, and MR spectroscopy, which is sensitive to small amounts of fat and has high accuracy but with limitations of difficulty to perform and to analyze, limited availability, high cost, small spatial sample region, and sampling error with repeated examinations.^{14,38}

When signal loss is present with chemical shift imaging, the presence of fat is confirmatory. The technique is limited,

however, secondary to several confounders, including magnet field inhomogeneities such as in the presence of iron, T2* decay, T1 bias (which refers to the different T1 weighting for fat versus water), and inclusion of only one spectral peak for fat when multiple smaller peaks exist and add to the fat signal. These confounders result in underestimation or lack of detection of fat. These effects are most dramatic at low fat levels, the range where screening for early disease would be important.^{37,39}

New MRI techniques continue to be developed to correct for these cofounders and also to better quantify the presence of fat to accurately grade steatosis. The benefit of these techniques is the potential to replace the “gold standard” for fat quantification, which currently is percutaneous biopsy, an invasive technique that samples only a small portion of the liver. These techniques may also serve as an early and accurate screening tool for asymptomatic but high-risk patients. These techniques result in accurate separation of signal created by mobile fat protons from all other mobile protons by calculating a proton density fat fraction.³⁷⁻³⁹ This fraction can be used to create a fat map of the entire liver that can be viewed with a color scale to demonstrate the variability of fat fractions throughout the

parenchyma. These maps are also useful in monitoring changes over time with treatment. Early results have demonstrated high correlation of these methods with MR spectroscopy and improved ability to detect smaller amounts of fat (<5%) where the transition lies from normal to clinically significant steatosis (>5.56%).^{40,41}

Hepatitis

Hepatitis is a general term used to describe acute or chronic inflammation of the liver. In general medical parlance, *hepatitis* refers to viral hepatitis, but diffuse parenchymal inflammation can result from numerous hepatic infectious or inflammatory processes. It can also be seen after inhalation, ingestion, or parenteral administration of a number of agents, including alcohol, acetaminophen, carbon tetrachloride, halothane, isoniazid, chlorpromazine, oral contraceptives, α -methyldopa, methotrexate, azathioprine, and 6-mercaptopurine.⁴²⁻⁴⁴

VIRAL HEPATITIS

The liver is almost invariably involved in all hematogenous viral infections. These include mononucleosis; herpes simplex; cytomegalovirus infection in patients with acquired immunodeficiency syndrome (AIDS); yellow fever in tropical countries; and rubella, adenovirus infection, and enterovirus infection in children. The term *viral hepatitis* is usually reserved for hepatic infections caused by a small group of hepatotropic viruses known as hepatitis A, B, C, D, and E. Viral hepatitis is the etiology for 60% of cases of fulminant hepatic failure in the United States.⁴²⁻⁴⁴

Clinical Findings

Viral hepatitis type A is an acute infection that occurs sporadically or epidemically and is transmitted by a fecal-oral route. Its incubation period is 15 to 50 days, and it most often has a benign self-limited course that does not cause chronic hepatitis and only rarely causes fulminant hepatitis.⁴²⁻⁴⁴

Viral hepatitis type B is the most common of the hepatotropic viruses worldwide. It is also the most versatile in its presentation and can cause an asymptomatic carrier state, acute hepatitis, chronic hepatitis, cirrhosis, fulminant hepatitis with massive hepatocyte necrosis, or HCC. Viral hepatitis type B is manifested within 30 to 180 days of infection by parenterally administered infected blood or by vertical transmission from mother to child at birth. There are more than 240 million carriers of the virus worldwide and 1.4 million in the United States.⁴²⁻⁴⁶

Hepatitis B viral infection is closely linked to the global distribution of HCC. In endemic areas, the annual incidence of HCC is 387 per 100,000 for men and 63 per 100,000 for women. In Europe and the United States, the carrier rate of hepatitis B virus is less than 1%. In Africa and Southeast Asia, the carrier rate is up to 10%. In high-incidence locales, HCC accounts for almost 40% of all cancers, as opposed to 2.3% in the West. Vertical transmission of the virus from infected mothers is the most common means of disease spread in these regions.⁴²⁻⁴⁴ Vaccination has been available since 1982 and is 95% effective.

Hepatitis C is caused by a parenterally transmitted RNA virus that affects 0.5% to 1% of normal volunteer blood donors in the United States. It now accounts for 90% of the cases of

hepatitis as a result of contaminated blood transfusions before standard screening. A routine blood test for anti-hepatitis C antibody has been developed, greatly improving transfusion safety. The use of unclean needles is also a major mode of transmission. Approximately 150 million people are chronically infected with hepatitis C worldwide.⁴⁵ The mean delay of the onset of symptoms and seropositivity is 22 weeks.⁴²⁻⁴⁴ Hepatitis C can cause either acute or chronic hepatitis; at least 50% of acute cases progress to chronic hepatitis. Chronic hepatitis C tends to be a silent, insidious disease; 10% to 20% of patients eventually develop cirrhosis.⁴²⁻⁴⁴

The hepatitis D virus (HDV), a defective virus that requires the presence of the hepatitis B virus (HBV) to exist, can be acquired either as a coinfection (occurs simultaneously) with HBV or as a superinfection in persons with existing chronic HBV infection. HBV-HDV coinfection has a more severe acute disease and a higher risk (2%-20%) for development of acute liver failure compared with those infected with HBV alone. Chronic HBV carriers who acquire HDV superinfection usually develop chronic HDV infection. Progression to cirrhosis is believed to be more common with HBV-HDV chronic infections than with HBV infection alone.⁴²⁻⁴⁴

Hepatitis E is a single-stranded RNA virus that is waterborne and transmitted by the fecal-oral route; it has an incubation period of 6 weeks. There is no chronic carrier state, and the disease is usually self-limited with a rate of fulminant hepatic failure of about 2%. The mortality and morbidity are significantly higher in pregnant women, with a mortality rate of 20%.

Patients with viral hepatitis typically present subacutely with fatigue, anorexia, nausea and vomiting, malaise, mild pyrexia, myalgias, photophobia, pharyngitis, cough, and coryza. These constitutional symptoms precede the onset of jaundice by 1 to 2 weeks. When jaundice appears, the patient's clinical condition improves, but the liver becomes enlarged and tender in 70% of cases. Splenomegaly is present in 20%. Complete clinical and biochemical recovery is usually seen in 3 to 4 months.⁴²⁻⁴⁴ If the inflammatory changes persist for more than 6 months, the patient is considered to have chronic hepatitis. The prognosis is often poor for these patients, who have jaundice and hepatosplenomegaly associated with an immune-mediated multisystem disease.

Pathologic Findings

On pathologic examination, the changes of acute viral hepatitis are virtually the same regardless of the offending agent. The entire liver is acutely inflamed, with centrilobular necrosis, hepatocyte necrosis, periportal infiltration by leukocytes and histiocytes, and reactive changes in the Kupffer cells and sinusoidal lining cells (Fig. 89-5). Centrilobular cholestasis and bile duct proliferation also occur.²

In chronic active hepatitis, the chronic periportal inflammatory changes extend into the liver parenchyma, producing necrosis and formation of intralobular fibrous septa. Chronic persistent hepatitis is a relatively benign condition characterized histologically by cellular infiltrates within the necrosis. In both disorders, definitive diagnosis is made by liver biopsy.²

Radiologic Findings

The diagnosis of viral hepatitis can usually be made on the basis of history, serologic markers, and liver function test abnormalities. Imaging is usually done to ensure that there is no obstructive component of the patient's hepatic dysfunction, to assess

for cirrhosis and its complications, to exclude focal hepatic abnormalities such as HCC, and to assess hepatic vascular patency.

Ultrasound

Ultrasound findings in acute hepatitis, although often present, are nonspecific. The major role of ultrasound in hepatitis is to exclude biliary obstruction as the cause of liver disease and to diagnose other major complications, such as ascites or vascular occlusion. In chronic viral hepatitis, ultrasound is also used to screen for the development of cirrhosis or HCC. Although its

Figure 89-5 Hepatitis: pathologic findings. Liver biopsy specimen shows so-called piecemeal necrosis typical of viral hepatitis.

sensitivity for both lags in comparison to CT and MRI, ultrasound is less expensive and more readily available.

In acute viral hepatitis, the liver and spleen are frequently enlarged. When parenchymal damage is severe, the parenchymal echogenicity is decreased and the portal venule walls are “brighter” than normal (Fig. 89-6). The increased sonographic contrast between the parenchyma and the periportal collagenous tissue is probably due to increased hepatic water, hydropic swelling of hepatocytes, and inflammatory cell infiltration. The increased hepatic water (periportal edema) accentuates the acoustic mismatch between the hepatocytes and the portal tracts.^{3,30,31} Also, the decreased attenuation of the liver allows greater sound penetration to “highlight” these vessels, with increased echogenicity of the walls of peripheral portal veins. This has been termed the centrilobular pattern or “starry sky” appearance. It has been observed in up to 60% of patients with acute hepatitis and is best appreciated in thin patients.^{3,31} This pattern is nonspecific and has also been reported in toxic shock syndrome, cytomegalovirus infection, idiopathic neonatal jaundice, leukemia, diabetic ketoacidosis, and lymphoma. Hepatomegaly is another nonspecific finding in patients with acute hepatitis.

When it is severe, chronic hepatitis produces increased parenchymal echogenicity and loss of mural definition of the portal veins. This is attributed to “silhouetting out” of the portal vein walls by the echogenic fibrotic and inflammatory process surrounding the lobules that abut the portal triads. These findings are nonspecific and can also be seen in patients with fatty infiltration and cirrhosis. One useful differentiating feature is the presence of adenopathy in the hepatoduodenal ligament in

Figure 89-6 Hepatitis: sonographic features. **A.** In a patient with acute hepatitis, sagittal scan of the right lobe of the liver shows diffusely decreased parenchymal echogenicity with accentuated brightness of the portal triads and periportal cuffing, the “starry sky” appearance. **B.** In a patient with chronic active hepatitis, there is increased inhomogeneous parenchymal echogenicity due to the inflammatory process surrounding the lobules that abut the portal triads. **C.** In viral hepatitis, the lymph nodes (cursors) draining the liver may become enlarged and serve as a useful marker to the efficacy of antiviral therapy. (B courtesy of Peter Cooperberg, MD, Vancouver, British Columbia, Canada.)

chronic active hepatitis, which has been attributed to direct spread of the hepatic inflammatory process.

Acute viral hepatitis can also be associated with thickening of the gallbladder wall. In early hepatitis, the gallbladder is hypertonic, whereas in patients more than 9 days after disease onset, the gallbladder is hypokinetic with a large volume and demonstrates a diminished response to a fatty meal.^{3,31}

Computed Tomography

The primary role of CT in patients with hepatitis is to assess for the development of cirrhosis and associated sequelae, including HCC. CT findings in hepatitis are usually nonspecific. Hepatomegaly, gallbladder wall thickening, and hepatic periportal lucency (Fig. 89-7) are the major CT findings in patients with acute viral hepatitis. This lucency is due to periportal fluid and lymphedema surrounding the portal veins and has also been reported in patients with AIDS, trauma, neoplasm, liver transplants, liver transplant rejection, and congestive heart failure. Early in the disease, the liver is enlarged and heterogeneous. Multiple regenerative nodules may be seen, and the liver becomes smaller and nodular with time as fibrosis increases and progresses to cirrhosis. CT has shown that hepatic necrosis is repaired by hypertrophy of regenerative nodules rather than by an increase in the number of nodules. These nodules give rise to the macronodular pattern of postnecrotic cirrhosis. Rarely, the nodules may be hypodense and simulate metastases on CT. Cirrhosis is discussed in detail later in this chapter.

In patients with chronic active hepatitis, lymphadenopathy is commonly found in the porta hepatis, gastrohepatic ligament, and retroperitoneum; it may be the only CT abnormality in a patient with severe hepatic dysfunction. CT can also follow the course of antiviral therapy by observing a reduction in lymph node size.

Magnetic Resonance Imaging

On MRI, acute hepatitis may show nonspecific findings such as heterogeneous signal intensity, most apparent on T2-weighted sequences, and a heterogeneous pattern of enhancement on

arterial-dominant phase spoiled gradient-echo images. This abnormal enhancement becomes more marked and can persist into the venous and delayed phases as the severity of disease increases. High signal intensity periportal edema can be seen on T2-weighted images. In both acute and chronic hepatitis, adenopathy in the lesser omentum may be the only abnormality identified.⁴⁷⁻⁵¹

In chronic hepatitis, MRI can provide information on the degree of histologic activity of disease and help monitor the response to therapy. Homogeneous or heterogeneous increase in signal intensity has been described on T2-weighted images and reflects the presence of inflammation or necrosis of the liver parenchyma. Early patchy enhancement patterns in patients with chronic hepatitis have been shown to be associated with significant parenchymal inflammatory reaction. Absence of this early patchy enhancement correlates with low inflammatory reaction.⁴⁸

In patients with chronic fibrosis associated with cirrhosis, there is progressive enhancement on delayed images due to leakage of gadolinium contrast from the intravascular into the interstitial space.⁴⁹

ALCOHOLIC HEPATITIS

Clinical Findings

Alcoholic liver disease is manifested as three distinct but overlapping entities: fatty liver, alcoholic hepatitis, and cirrhosis. The first is reversible with abstinence; the last two are progressive and shorten life expectancy. Alcoholic hepatitis is part of the spectrum of alcoholic liver disease in which a major drinking binge produces acute liver cell necrosis. These changes are usually superimposed with steatosis or already developing cirrhosis from chronic alcohol use. In most cases, cessation of alcohol consumption and adequate nutrition may ameliorate the patient clinically and histologically. Repeated bouts of acute alcoholic hepatitis are associated with a 10% to 20% risk of death and a 35% risk for development of cirrhosis. Patients usually have fever and neutrophil leukocytosis and may present with malaise, anorexia, weight loss, upper abdominal pain, tender hepatomegaly, and jaundice.⁵²⁻⁵⁶

Pathologic Findings

The specific mechanism of alcohol-induced hepatotoxicity is uncertain despite extensive research on both biochemical and immunologic models of hepatocyte damage. Theories range from peroxidation of cell membranes to modification of membrane permeability to sensitized T cells directed against hepatocytes. The histologic hallmark of alcoholic hepatitis consists of Mallory bodies, which are eosinophilic cytoplasmic inclusions that take the form of “candle droppings” in ballooned, degenerating hepatocytes. In most cases, alcoholic hepatitis is accompanied by pericellular and perivenular fibrosis, again suggesting that this is a precursor to cirrhosis.⁵²⁻⁵⁶

Radiologic Findings

In patients with alcoholic hepatitis, imaging is done to exclude obstructive biliary disease and neoplasm and to evaluate parenchymal damage noninvasively.

Ultrasound

In acute alcoholic hepatitis, the liver is hyperechoic secondary to fatty infiltration. The liver may be enlarged early in the

Figure 89-7 Acute hepatitis: CT findings. CT scan shows periportal edema (arrow) highlighting the intrahepatic blood vessels.

disease process, but it becomes atrophic as cirrhosis ensues. Because cirrhosis and fatty infiltration appear similar sonographically, both with heterogeneous echotexture, increased echogenicity, and sound attenuation, CT and MRI are more sensitive in their differentiation.^{3,31}

Computed Tomography

CT may show fatty infiltration in a normal-sized, enlarged, or atrophic liver, depending on the extent of prior liver injury.⁵⁷ As hepatitis progresses to cirrhosis, alcoholic cirrhosis characteristically demonstrates a micronodular pattern as well as enlargement of the caudate lobe and of the right posterior hepatic lobe notch of greater proportion than in other causes of hepatitis. HCC develops at a 5-year cumulative rate of 8%.⁵⁸ Biliary stasis and development of gallstones as well as periportal lymphadenopathy are common in alcoholic hepatitis.

Magnetic Resonance Imaging

Similar to CT, MRI depicts hepatic size and morphology and can be useful in depicting hepatic fibrosis, steatosis, and cirrhosis. MRI is also the most sensitive modality for detection of HCC. Phosphorus 31 MR spectroscopy has shown that livers of patients with alcoholic hepatitis and cirrhosis can be differentiated from normal liver and from each other on the basis of intracellular pH and absolute molar concentration of adenosine triphosphate. Hepatocytes are more alkaline than normal in alcoholic hepatitis and more acidic than normal in cirrhosis.⁴⁷

Toxin- and Drug-Induced Liver Disease

Although drug-induced liver disease represents a small proportion of all adverse drug effects, it accounts for 2% to 5% of hospital admissions for jaundice in the United States and up to 43% of admissions for “acute hepatitis.”

Anesthetics (halothane, enflurane), anticonvulsants (phenytoin), anti-inflammatory agents (gold, clometacin, sulindac), analgesics (acetaminophen), hormonal derivatives (danazol), antidepressant or anti-anxiety drugs (amitriptyline, amineptine), antimicrobials (isoniazid, amoxicillin, sulfamethoxazole-trimethoprim), antiulcer drugs (cimetidine, ranitidine), hypolipidemic agents (nicotinic acid, gemfibrozil), drugs for inflammatory bowel disease (sulfasalazine), and cardiovascular drugs (quinidine, amiodarone) have all been associated with parenchymal liver disease.⁵⁶ Liver damage may be severe, exemplified by 20% to 50% of cases of fulminant hepatic failure being attributed to drugs such as halothane, acetaminophen, α -methyldopa, and phenytoin.⁵⁶

Certain drugs and other chemical agents are capable of producing a wide variety of clinical consequences ranging from very mild liver disease to hepatic failure. The spectrum of hepatotoxicity varies from acute, dose-related, predictable, hepatocellular necrosis to chronic inflammatory disorders ranging from mild chronic persistent hepatitis to severe chronic active hepatitis. In addition, vascular disorders, such as peliosis hepatis and the Budd-Chiari syndrome, and neoplastic lesions, such as angiosarcomas and benign hepatic adenomas, are associated with certain naturally occurring toxins such as “bush teas” and aflatoxins in peanuts, oral contraceptives and anabolic steroids, industrial toxins such as vinyl chloride (Thorotrast), and organic arsenic found in pesticides.⁵⁶

CHEMOTHERAPY TOXICITY

The liver plays a key role in the metabolism of most medications that are either parenterally administered or gastrointestinally absorbed into the portal venous system and therefore is vulnerable to possible injury as a result of exposure. Hepatic deterioration resulting from chemical toxicity can be a diagnostic dilemma in oncology patients with known liver metastases. It is often clinically difficult to differentiate chemotherapy-induced parenchymal injury from other processes, including tumor progression, tumor necrosis, portal and hepatic venous thrombosis, hepatic ischemia and infarction, transfusion reactions, viral hepatitis, and segmental biliary obstruction by tumor. Radiology plays a key role in elucidating the cause of hepatic dysfunction in these patients.

Clinical or subclinical hepatotoxicity is common during systemic chemotherapy. A large series of patients with breast cancer demonstrated that 77% of those receiving systemic adjuvant chemotherapy and 82% of those being treated for metastatic breast cancer, all with normal pretreatment liver function test results, developed abnormal hepatic laboratory values during and after therapy.⁵⁴⁻⁵⁶ The mechanism of chemotherapy agents often involves prevention or retardation of cell division, which can also damage liver cells and diminish immune response. Methotrexate is often associated with steatosis, fibrosis of the portal triads, and eventually cirrhosis. Corticosteroids and L-asparaginase may produce steatosis. Dacarbazine and 6-thioguanine can cause thrombosis of intrahepatic portal veins, producing a Budd-Chiari-like appearance. Azathioprine and 6-mercaptopurine therapy may result in intrahepatic cholestasis and variable degrees of parenchymal cell necrosis. Intra-arterial infusion of floxuridine may cause chemical hepatitis and biliary strictures simulating sclerosing cholangitis. Mithramycin is perhaps the most hepatotoxic drug used in chemotherapy and is associated with acute parenchymal necrosis. Bevacizumab (Avastin) has been associated with hepatic veno-occlusive disease.⁵⁴

On cross-sectional images, the findings are fairly nonspecific and identical to those seen in other liver injuries: hepatomegaly, cirrhosis, and fatty infiltration. Cross-sectional imaging, however, is vital in excluding biliary obstruction or worsening liver metastases as the cause of the patient's hepatic dysfunction. MRI and MR spectroscopy may be helpful in evaluating parenchymal injury. In vitro and laboratory MR experiments have shown that carbon tetrachloride produces water and sodium retention, which can be detected by sodium 23 and proton imaging. Cellular damage is most prominent in the periportal regions, which may be seen as a high signal intensity on T2-weighted images and high sodium signal intensity on spectroscopy.⁴⁷

AMIODARONE TOXICITY

Hepatotoxicity caused by amiodarone is well documented and is usually manifested by mild asymptomatic elevation of serum transaminase levels. When more severe injury occurs, it can simulate alcoholic liver disease with steatosis, Mallory bodies, and cirrhosis. The length of treatment with amiodarone before recognition of hepatic damage can range from several weeks to several years.⁵⁶

The sonographic findings in this disorder are nonspecific and related to steatosis or cirrhosis. The CT appearance

Figure 89-8. Amiodarone hepatotoxicity. Non-contrast-enhanced CT scan of a cardiac patient who had been taking amiodarone demonstrates a liver with an abnormally high attenuation compared with the spleen. Note how the hepatic blood vessels are highlighted by the dense parenchyma. The appearance is indistinguishable from that of hepatic iron overload. There is a right-sided pleural effusion.

(Fig. 89-8), however, is distinctive. When this drug or its metabolites, which contain iodine, accumulate in sufficient quantities in the liver, increased parenchymal attenuation simulating hemochromatosis can be identified.

Radiation-Induced Liver Disease

CLINICAL FINDINGS

Although the liver was once believed to be relatively radioresistant, hepatic morphologic and functional alterations have been observed after radiation therapy since the 1960s and are now established as a complication.

The liver is usually not the intended target for radiation treatment; its exposure occurs when it is unavoidably included in the treatment portal for primary malignant neoplasms of the breast, esophagus, stomach, pancreas, and lymphoma. Patients who receive greater than 30 Gy of total liver radiation are at risk of developing radiation-induced hepatitis.^{56a} Nearly 75% of patients receiving whole liver irradiation have liver function test abnormalities.^{1,2} The classic signs and symptoms of acute hepatic radiation injury are hepatomegaly and ascites. Such effects are not observed when the area of irradiated hepatic tissue is small. High doses of radiation to the liver during childhood can result in hepatic atrophy. In children, restricted development can occur in other structures included in the radiation field, such as the kidney or vertebral bodies.

Radiation damage can also occur from local effects of targeted radiation therapy to the liver with yttrium 90. These microspheres are delivered angiographically to treat either a primary malignant neoplasm or metastatic disease to the liver and inflict a combination of local intense radiation and embolic devascularization. Although local radiation effects can occur, a

Figure 89-9. Radiation-induced hepatic injury. Contrast-enhanced CT scan shows a sharply defined region (arrows) of hepatic hypoattenuation near the dome of the liver. This patient had received external beam radiation therapy for lung carcinoma.

major advantage of targeted radiation is that radiation-induced diffuse liver disease with hepatomegaly and ascites is extremely rare.⁵⁹

PATHOLOGIC FINDINGS

Radiation hepatitis is characterized by massive panlobular congestion, hyperemia, hemorrhage, and mild proliferative change in the sublobular central veins. Most of the acute findings are sequelae of blood flow stasis secondary to injury of these veins. Complete clinical recovery is typically seen within 60 days, but there may be irreversible hepatocyte loss, fat deposition, fibrosis, or obliteration of the central veins.^{1,2}

RADIOLOGIC FINDINGS

With ultrasonography, geographic areas of radiation injury are hypoechoic relative to the remainder of the liver. This is likely the result of localized hepatic congestion or edema. These changes are more easily detected sonographically in patients with a background of hepatic steatosis resulting from chemotherapy or other causes, which accentuates the hypoechoic areas of radiation injury.^{28,31}

CT performed within several months of the radiation therapy shows a sharply defined band of low attenuation corresponding to the treatment port (Fig. 89-9). This is due to edema or fatty infiltration of the involved area. If hepatic congestion is severe, it may appear heterogeneous and possibly simulate other processes, such as malignant neoplasms. In patients with a background of diffuse hepatic steatosis, the irradiated hepatic area may appear as a region of relatively increased attenuation. This may be due to loss of fat accumulation in the irradiated hepatocytes or regional edema, with the water content demonstrating higher attenuation in comparison with the steatotic parenchyma. During a period of weeks, the initially sharp borders of the irradiated zone become more irregular and indistinct as the peripheral areas of parenchyma begin to regenerate.

Eventually, the irradiated area may become atrophic, demonstrated by volume loss. Radiation effects from yttrium 90 therapy can be manifested with hyperenhancement or hypoenhancement of a portion of the liver and chronically result in atrophy, similar to external beam radiation. The difference is that the distribution of the changes occurs in a hepatic arterial territory distribution rather than along a sharply marginated line. Extensive fibrosis from any radiation source can also potentially cause portal hypertension. Biliary strictures and radiation-induced cholecystitis can rarely occur.⁵⁹

Radiation hepatitis on MRI is manifested as geographic areas of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images secondary to increased water content as determined by proton spectroscopic imaging.⁴⁷ Similar to CT, a distinctly sharp margin between the normal and abnormal liver parenchyma and appropriate clinical history are useful in making the specific diagnosis of postradiation changes.

Hemosiderosis and Hemochromatosis

The body normally contains 2 to 6 g of iron, 80% of which is functional iron in the form of hemoglobin, myoglobin, and iron-containing enzymes. The other 20% is in the storage form as either hemosiderin or ferritin and is normally stored within the reticuloendothelial system, which includes Kupffer cells within the liver and macrophages within the spleen and bone marrow. When it is present in excess amounts, iron is deposited into additional organs, where it can potentially cause dysfunction. Increased iron deposition without parenchymal organ damage is called hemosiderosis and is usually seen with body iron stores between 10 and 20 g.⁶⁰⁻⁶⁴

Hemochromatosis is an iron overload disorder that results in structural and functional impairment of the involved organs. In these cases, body iron accumulation may reach 50 to 60 g. Primary hemochromatosis is an inherited disorder characterized by abnormally increased iron absorption by the mucosa of the duodenum and jejunum that leads to excessive delivery of iron into the portal venous system. Iron accumulates within the liver; once it is saturated, the iron spills into the systemic circulation, where it binds to transferrin. Iron is then deposited preferentially into organs with a high transferrin receptor density, including the pancreas, heart, thyroid, gonads, pituitary gland, and skin, and generally spares the reticuloendothelial system. Secondary hemochromatosis develops in three groups of patients: those with high iron intake (e.g., prolonged consumption of medicinal iron, iron-laden wine, kaffir beer, multiple blood transfusions); anemic patients with ineffective erythropoiesis and multiple blood transfusions (e.g., thalassemia major, sideroblastic anemia); and patients with liver disease in alcoholic cirrhosis and after portacaval shunts.⁶⁰⁻⁶⁴ Iron liberated from red blood cells as a result of multiple transfusions or hemolytic anemias is taken up primarily by phagocytes within the liver, spleen, bone marrow, and lymph nodes, and organ function is generally preserved (hemosiderosis).⁶⁰⁻⁶⁴ Unlike in primary hemochromatosis, reticuloendothelial cell iron overload resulting from transfusions and rhabdomyolysis is usually of little clinical consequence; however, if it is prolonged or severe, such as in thalassemia or sickle cell disease, iron overload can cause a similar pattern of organ dysfunction and is then referred to as secondary hemochromatosis.

CLINICAL FINDINGS

The classic triad of hemochromatosis consists of micronodular pigment cirrhosis, diabetes mellitus, and hyperpigmentation. Patients with primary hemochromatosis usually present in the fourth or fifth decade of life because it takes many years to accumulate sufficient iron (20-40 g) to result in symptoms. There is a 10:1 male predominance in fully developed hemochromatosis. Women are protected from this disorder by the iron loss that occurs during normal menstruation, pregnancy, and lactation.⁶⁰⁻⁶⁴

The liver is the first organ damaged in hemochromatosis, and hepatomegaly is present in 95% of symptomatic cases. Splenomegaly is present in nearly 50% of cases. Arthropathy of the small joints of the hands develops in 25% to 50% of cases and may antedate other symptoms. Cardiac involvement is the presenting complaint in about 15% of cases and is most commonly manifested as congestive heart failure in young adults. Loss of libido, loss of body hair, and testicular atrophy resulting from failure of gonadotropin production are also common. Increased melanin deposition in the basal layers of the epidermis leads to hyperpigmentation, resulting in so-called bronze diabetes in these patients.⁶⁰⁻⁶⁴

The life expectancy of untreated patients with idiopathic hemochromatosis after the disease becomes clinically manifested is 4.4 years. The most common causes of death in these patients are cardiac failure (30%), hepatic coma (15%), hematemesis (14%), HCC (14%), and pneumonia (12%). Removal of iron by repeated phlebotomy and use of iron chelators increases the 5-year survival from 33% to 89%. The liver and spleen decrease in size, liver function test results return to normal, pigmentation decreases, glucose tolerance normalizes, and cardiac function improves with successful therapy. Once cirrhosis occurs, liver injury is irreversible, and about one third of patients develop HCC as a late sequela despite adequate therapy. The risk for development of HCC is increased more than 200-fold in patients with hereditary hemochromatosis. It is therefore important to diagnose this disorder early, in the pre-cirrhotic stage.⁶⁰⁻⁶⁴ Early diagnosis, however, is often difficult because there may be considerable hepatic iron accumulation before the patient becomes symptomatic. CT and MRI may fortuitously detect iron overload, and these modalities are useful in confirming the diagnosis in patients with equivocal laboratory data. Classically, the serum iron level is greater than 250 mg/dL (normal, 50-150 mg/dL), serum ferritin value is above 500 ng/dL (normal, below 150 ng/dL), and transferrin saturation approaches 100% (normal, 25%-30%) in patients with hemochromatosis. Transferrin saturation is the earliest and most sensitive indicator of increased iron stores. Virtually all patients older than 20 years have levels greater than 50%.⁶⁰⁻⁶⁴ Serum ferritin levels, however, are nonspecific and influenced by the presence of inflammatory states, neoplastic disorders, and other hepatocellular diseases. Imaging or biopsy helps clarify the results of these sensitive but somewhat nonspecific tests.⁶⁰⁻⁶⁴

PATHOLOGIC FINDINGS

The principal features of classic primary hemochromatosis are excessive intracellular ferritin and hemosiderin aggregates as the result of excessive intestinal absorption of iron. Iron first accumulates in periportal hepatocytes and then in the lobular

Figure 89-10 Iron overload: histologic findings. Prussian blue stain showing extensive iron deposition.

Figure 89-11 Iron overload: gross pathologic findings. Autopsy specimens show iron deposition in the liver, pancreas, and a lymph node in a patient who died with hemochromatosis. Note the dark brown hue of these organs.

hepatocytes, Kupffer cells, and biliary epithelium. When the liver becomes overwhelmed, iron enters the systemic circulation bound to transferrin and subsequently is deposited into organs with high transferrin-binding receptors including the pancreas, heart, joints, endocrine glands, and skin, in decreasing order of severity (Figs. 89-10 and 89-11). Free iron within cells causes formation of free radicals and results in cell damage leading to inflammation, cell death, and fibrosis. Because the liver contains up to one third of the total body store of iron, it is the organ most profoundly damaged in hemochromatosis. At gross pathologic examination, early in the disease, the liver is slightly larger than normal, dense, and chocolate brown due to ferritin with focal golden yellow granules of hemosiderin. Progressive deposition leads to slowly evolving liver damage and development of fibrous septa similar to those in alcoholic cirrhosis, ultimately producing micronodular cirrhosis. Late in disease, the liver size is only slightly diminished, and fat is usually absent. Liver biopsy can be used to provide an objective measurement of hepatic iron concentration (normal, 7 to 100 pg/100 mg). With primary hemochromatosis, the pancreas is intensely pigmented and demonstrates diffuse interstitial fibrosis resulting

Figure 89-12 Iron overload: CT findings. The attenuation of the liver is diffusely increased secondary to intraparenchymal iron deposition.

in a deficiency of exocrine and, to a greater extent, endocrine function. Hemosiderin is found in both acinar and islet cells, and some correlation is reported between the degree of iron deposition in pancreatic islets and the severity of endocrine dysfunction.⁶⁰⁻⁶⁴

RADIOLOGIC FINDINGS

Plain Radiographs

Rarely, diffuse, homogeneously increased density of the liver may be seen on plain abdominal radiographs in patients with hemochromatosis. Skeletal abnormalities include chondrocalcinosis and degenerative arthritis in the second and third metacarpal heads. Chondrocalcinosis occurs in two thirds of patients and is associated with cartilage narrowing.

Ultrasound

The sonographic appearance of hemochromatosis is nonspecific and related to fibrosis and cirrhosis. Parenchymal iron deposits are too small to be reflective, so ultrasound has no role in the early diagnosis of hepatic iron overload.

Computed Tomography

CT has had a significant impact on the noninvasive diagnosis of excess hepatic iron deposition, although it has a limited sensitivity (63%) and high specificity (96%).⁶⁵ The normal density of the liver is between 45 and 65 HU on noncontrast scans obtained at 120 kVp. On CT, in patients with hemochromatosis, the liver demonstrates homogeneously increased density with an attenuation of greater than 72 HU (Fig. 89-12). The increased attenuation highlights the lower attenuation hepatic and portal veins on unenhanced CT. As discussed elsewhere in this chapter, a similar, diffuse pattern of increased attenuation can be seen in patients treated with amiodarone and in patients with glycogen storage disease that can be indistinguishable from iron overload with CT. Other causes of high parenchymal attenuation that are usually inhomogeneous or focal include calcification resulting from shock liver, exposure to Thorotrast, prior

intravasation of enteric barium, gold therapy administration for treatment of rheumatoid arthritis, and, rarely, Wilson's disease and chronic arsenic poisoning. Clinical history and the lack of homogeneity in these entities are useful in differentiating these from iron accumulation.⁶⁶ High density may also be seen on noncontrast CT in siderotic nodules of cirrhosis.

Measurement of the liver attenuation with CT is confounded by the presence of other diffuse liver processes, particularly hepatic steatosis. The fat decreases the attenuation value, which masks the increase in density seen from iron accumulation. The use of dual-energy CT has been proposed as a method with accuracy similar to that of MRI for the detection of iron in the setting of hepatic steatosis.⁶⁷

For accurate assessment for malignant disease in patients with iron accumulation, it is particularly important to obtain a noncontrast sequence. The high attenuation of the background liver parenchyma can decrease the conspicuity of contrast-enhancing masses, and the noncontrast images may best demonstrate the attenuation difference between a hypoattenuating mass and high-attenuation background parenchyma. Nonspecific changes of cirrhosis and portal hypertension with end-stage hemochromatosis can also be readily depicted with CT.

Magnetic Resonance Imaging

MRI is the most sensitive and specific imaging test for the demonstration of hepatic iron overload and for follow-up of patients undergoing treatment (Figs. 89-13 and 89-14). In primary hemochromatosis, MRI shows dramatic reduction in the signal intensity of the liver (90%). This signal loss is due to the large paramagnetic susceptibility of ferritin and hemosiderin-iron-oxyhydroxide crystals, which contain ferric ions (Fe^{3+}), that profoundly shortens both the T1 and T2 relaxation times of the adjacent protons within the liver. This paramagnetic effect is more conspicuous on T2-weighted images and is most profound on T2*-weighted images, both clinically used to assess for iron. When iron concentrations within the liver are elevated, the T2-shortening effect predominates, accounting for the diminished hepatic signal intensity. Iron overload can sometimes be recognized in the heart and pancreas by diminished signal intensity, as seen in the liver.^{25-27,42} In reticuloendothelial overload, decreased signal intensity is seen on T2 within the spleen and bone marrow. In hemolytic anemias, the renal cortex also occasionally has decreased T2-weighted signal intensity. The paramagnetic effect increases as the echo time increases.

On T1 in-phase and opposed-phase gradient-echo sequences, signal loss is greater on the T1 in-phase imaging because of its longer echo time in comparison with the opposed-phase imaging. This is opposite to the pattern of signal loss seen in the presence of microscopic fat, when signal loss occurs on the opposed-phase sequence. Focal iron deposition may also be demonstrated by MRI, such as in siderotic nodules seen in cirrhosis.

The normal hepatic parenchyma has a slightly increased T2- and T2*-weighted MR signal intensity compared with that of the kidney and paraspinal musculature, which can be used for comparison both qualitatively and quantitatively. MRI can be helpful to distinguish the parenchymal overload that occurs in primary hemochromatosis from reticuloendothelial cell iron overload (see Figs. 89-13 and 89-14). Whereas abnormally decreased T2 signal intensity is seen in both, in primary hemochromatosis, decreased signal intensity is observed within the pancreas and heart; in reticuloendothelial cell iron overload, decreased signal intensity of the spleen, bone marrow, and occasionally lymph nodes is observed with normal signal intensity of the other organs.^{47-49,68}

MRI can also be used to diagnose and to monitor treatment of patients with parenchymal iron overload. Quantitative assessment can be performed with two techniques, signal intensity ratio and relaxometry. The signal intensity ratio method uses T2- and T2*-weighted imaging at multiple different echo times or flip angles and measures the signal intensity of the liver and of a reference tissue that will not accumulate iron, usually the paraspinal muscle.⁶⁹ The mean signal intensity of the liver is divided by the mean signal intensity of the reference tissue. For estimated concentration of more than 85 $\mu\text{mol/g}$, the positive predictive value for hemochromatosis is 100%; for less than 40 $\mu\text{mol/g}$, the negative predictive value for hemochromatosis is 100%.⁶⁸ Complete signal loss at concentrations above 300 $\mu\text{mol/g}$ precludes accurate measurements with iron overload above these levels. Other limitations of this technique include the need for breath holding and inhomogeneity of signal intensity resulting from the presence of fat or minor variations in the location of selected regions of interest between sequences. In the relaxometry method, the signal intensity of the liver is measured as a function of increasing echo time, which is used to calculate a signal decay constant. Iron concentration is inversely proportional to these values.⁷⁰ Technical factors include calibration for the field strength and choosing a

Figure 89-13 Hemosiderosis: MR findings. **A.** Axial T1-weighted image shows marked decrease in signal intensity of the liver and spleen due to iron deposition into the Kupffer cells of the liver and the reticuloendothelial cells of the spleen. **B.** Axial T1-weighted image of the pelvis in the same patient shows markedly decreased signal intensity within the pelvic bones due to the deposition of iron into bone marrow reticuloendothelial cells.

Figure 89-14 Hemochromatosis: MR findings. Two different patients with hemochromatosis. **A.** MR scan shows a cirrhotic, markedly hypointense liver surrounded by ascites. The spleen is spared because it is composed primarily of reticuloendothelial cells, which do not accumulate iron in hemochromatosis, an important differentiating feature from hemosiderosis. **B.** Scan obtained caudal to **A** shows low signal intensity of the pancreas; the acinar cells do accumulate iron. In a different patient, T1-weighted (**C**) gradient-echo (**D**) images of the upper abdomen show marked hypointensity of the liver and spleen due to the deposition of iron in the hepatocytes of the liver and the acinar cells of the pancreas. Notice the low signal intensity Gamna-Gandy bodies in the spleen, secondary to hemosiderin deposition, a finding seen in portal hypertension with microhemorrhages into the splenic parenchyma.

clinical range of echo time values. The choice of parameters used for measurement and the pulse sequence design also affect the calculated result. For both methods, normal variability within tissues, concurrent processes such as steatosis and fibrosis, choice of voxel size and location, technical factors related to MRI hardware and technique, and mathematical models used for data calculation all potentially limit the accuracy of iron quantification.⁷¹⁻⁷⁵

Glycogen Storage Disease

CLINICAL AND PATHOLOGIC FINDINGS

The liver has a major role in the synthesis and storage of glycogen as well as its ultimate catabolism into glucose. Among inherited disorders of glycogen metabolism, types Ia, Ib, II, III, IV, VI, and IX affect the liver and are manifested with hepatomegaly.⁷⁶ Type Ia (von Gierke's disease) is the most common subtype to affect the liver. It is due to a deficiency of glucose-6-phosphatase in the liver and kidneys, which results in excessive glycogen deposition in the hepatocytes and proximal renal tubules. On pathologic examination, intracytoplasmic accumulations of glycogen and small amounts of lipid are found. Patients clinically demonstrate failure to thrive, hypoglycemia, hyperlipidemia, hyperuricemia, stunted growth, hepatomegaly, and nephromegaly. Hepatic adenomas are much more common than in the normal population, and the presence of more than 10 hepatic adenomas, known as adenomatosis, is seen in up to 60% of patients with type Ia glycogen storage disease.

Adenomas are also seen in glycogen storage disease types Ib and III. Increase in the size and number of adenomas increases the risk for associated hemorrhage. Much less commonly, HCCs can occur from malignant degeneration of an adenoma. Both processes are thought to result from hepatic exposure to chronic hormonal stimulation resulting from the chronic hypoglycemia. Types III and IV glycogen storage disease can progress to cirrhosis. Imaging surveillance of these patients is useful to evaluate for complications of the disease, including hemorrhage and malignant transformation.

RADIOLOGIC FINDINGS

Ultrasound

On sonographic evaluation, the liver is enlarged with increased echogenicity and beam attenuation, presumably from fatty infiltration and possibly contributed to by the excess glycogen deposition. Adenomas are common and can appear well circumscribed and may be hypoechoic, isoechoic, or hyperechoic in relation to the remainder of the liver. Increased sound transmission with refractile shadowing at the tumor margins is commonly seen. These findings are related to the paucity of fat and glycogen in the adenomas compared with the rest of the involved liver. These sonographic features are unique to adenomas in patients with glycogen storage disease, whereas adenomas from other causes tend to contain more fat in comparison to the background liver parenchyma. Change in the sonographic appearance of adenomas over time may reflect malignant degeneration or hemorrhagic necrosis.^{28,30} HCC can occur, and

any new or significantly changing mass should be further evaluated with contrast-enhanced CT or MRI.

Computed Tomography

The CT density of the liver in glycogen storage disease is altered by two processes with conflicting imaging effects: hepatic attenuation is increased by glycogen storage and decreased by fatty infiltration (Fig. 89-15A, B). Which appearance predominates within the liver depends, therefore, on the predominant underlying pathologic process. In addition to the liver, the spleen and kidneys are typically enlarged and the renal cortex may appear dense secondary to glycogen deposition. On noncontrast CT, hepatic adenomas are hypodense compared with normal liver and spuriously hyperdense if there is concomitant fatty infiltration. Unenhanced CT may also demonstrate hemorrhage within an adenoma. Adenomas are also usually well circumscribed and rarely have calcification. After the administration of contrast material, adenomas usually are hypervascular to the liver parenchyma on arterial phase imaging and nearly isoattenuating during the portal venous phase. Adenomas should remain stable in size or show slow growth on follow-up examination. Although distinction of adenomas from HCCs may be challenging on the basis of imaging morphology alone, malignant degeneration should be suspected if there is rapid growth or density change with a focal mass. Clinical assessment with surveillance of α -fetoprotein can also be used to detect development of malignancy and should not be elevated with the presence of adenomas alone.⁷⁷

Magnetic Resonance Imaging

On MRI, the appearance of adenomas varies but in general is heterogeneously hyperintense on T1- and T2-weighted imaging.

Focal areas of hypointensity may represent old hemorrhage or calcification. The presence of microscopic fat demonstrates focal signal intensity loss on the T1 opposed-phase sequence in comparison with the in-phase sequence⁷⁷ (Fig. 89-15C). Enhancement on hepatobiliary phase imaging with liver-specific gadolinium agents is not expected, which, however, does not help differentiate an adenoma from a dysplastic or malignant mass.⁷⁸

Amyloidosis

CLINICAL AND PATHOLOGIC FINDINGS

Amyloidosis is a systemic process whereby insoluble protein aggregates accumulate in various organs throughout the body. Several categories of amyloidosis exist, all of which can affect the liver. Primary amyloidosis results from overproduction by the bone marrow, such as in multiple myeloma. Secondary amyloidosis is due to chronic inflammatory disease. A rare familial form of amyloidosis also exists. Hepatic infiltration and enlargement are frequently found in patients with systemic amyloidosis, but significant liver disease is rare. Amyloid within the liver is deposited within spaces of Disse and then progressively encroaches on adjacent hepatic parenchymal cells and sinusoids. Cellular replacement of large areas of liver parenchyma may occur, giving the liver at gross pathologic examination a pale, waxy gray, firm appearance. Hepatic function is usually preserved despite marked amyloid infiltration. When amyloidosis is severe, it may be clinically symptomatic, manifested with right upper quadrant pain caused by stretching of Glisson's capsule, pruritus, ascites, malaise, weight loss, intrahepatic cholestasis, or portal hypertension.⁷⁹⁻⁸²

Figure 89-15 von Gierke's disease: imaging findings. **A.** Unenhanced CT scan of the liver shows diffuse increase in the density of the liver due to glycogen deposition. Three fat-containing adenomas (arrows) are present. **B.** Contrast-enhanced scan shows that these adenomas (arrows) are hypervascular. **C.** Axial T1-weighted MR scan shows high signal intensity fat within the adenoma in the left lobe (arrow).

RADIOLOGIC FINDINGS

Radiologic findings of amyloidosis are mostly nonspecific. On sonographic evaluation, the liver is enlarged and inhomogeneous in echotexture.^{83,84} On CT, findings also include hepatomegaly, and areas of low attenuation can occasionally be seen in focal areas of amyloid deposition. Calcification, also nonspecific, can also be present. Delayed contrast enhancement may be seen in the involved areas because of vascular and sinusoidal infiltration. A specific pattern of hepatomegaly with focal triangular enlargement near the falciform ligament and pointed surface anteriorly has been suggested.⁸⁵ Concomitant abnormalities seen in the spleen, including enlargement, decreased attenuation, and possible calcification, are helpful in differentiating amyloid deposition from hepatic neoplasm and fatty infiltration but are not often present.

On MRI, patients with primary amyloidosis demonstrate decreased T2 signal intensity within the spleen and adrenal glands and increased T2 signal intensity of the pancreas in comparison with normal individuals. Signal intensity within the liver may appear normal or increased on T1 (etiology unknown); however, T2 intensity is not significantly changed within the liver.^{84,85} Suggestion of delayed or absent contrast enhancement with liver-specific contrast agents has been suggested as a way to identify focal areas of amyloid deposition.⁸⁶

Wilson's Disease

CLINICAL AND PATHOLOGIC FINDINGS

Wilson's disease, also called hepatolenticular degeneration, is an autosomal recessive inherited disorder of copper metabolism. Copper is balanced within the body by regulation of its excretion and is protein bound within the serum. In Wilson's disease, there is a copper-transporting enzyme mutation that is manifested with decreased biliary excretion of copper, excessive absorption of copper from the gastrointestinal tract, abnormal urinary excretion of copper, and decreased levels of ceruloplasmin, the serum protein to which 95% of body copper is bound. Copper accumulates in hepatocytes until all the binding sites are used, at which point unbound copper causes oxidative damage. Accumulation then occurs in other organs, including the basal ganglia, renal tubules, cornea, bones, joints, and parathyroid glands.⁸⁷⁻⁸⁹

Clinical presentation can vary secondary to different mutations and degree of dysfunction of the copper-transporting adenosine triphosphatase; onset of the disease occurs as early as 5 years to as late as 40 years of age. Liver disease with a completely nonfunctioning enzyme most often is manifested in childhood or early adolescence with signs and symptoms including fatigue, hepatosplenomegaly, variceal bleeding, ascites, and encephalopathy. Hemolytic anemia can occur by a mechanism thought to be due to hemoglobin damage secondary to serum copper accumulation. This can result in acute fulminant hepatic failure.

The onset of neurologic symptoms usually occurs later, in early adulthood after cirrhosis is present. If hepatic changes remain subclinical, the patient may present with an asymmetric tremor, ataxia, speech disturbance, personality changes, and Parkinson-like symptoms including decreased movement and facial expression.⁹⁰ Kayser-Fleischer rings are green to brown copper deposits in the cornea, and their presence is a helpful

diagnostic finding in 98% of untreated patients. A slit-lamp examination is warranted in any patient with this suspected diagnosis of Wilson's disease.⁸⁷⁻⁸⁹

Laboratory diagnostic tests can be helpful in differentiating Wilson's disease from other hepatic diseases. Low serum ceruloplasmin concentration (<50 mg/100 mL) is present in 95% of cases and highly suggestive of Wilson's disease. Urinary copper (>100 µg/day) is elevated and can be useful in diagnosis and treatment monitoring. Liver aspartate transaminase, although nonspecific, is also elevated early in the disease. Genetic testing in patients with a family history can be performed.

On pathologic examination, electron microscopy of liver biopsy specimens shows fat droplets, nuclear glycogen deposits, and cellular necrosis. Inflammatory cells accumulate, and eventually fibrosis, loss of hepatic architecture, and cirrhotic changes are seen. Hepatic copper content is high (>250 µg/g dry weight; normal is <55 µg/g),⁹¹ which is concentrated in the sinusoidal and periportal distribution. Copper initially accumulates in the cytoplasm, followed by lysosomes. Morphologic abnormalities of the mitochondria are also seen. Marked elevation of hepatic copper can also be seen in the setting of chronic cholestasis but can usually be differentiated from Wilson's disease with clinical information and biliary obstruction seen with imaging.^{92,93}

The difficulty in the early recognition of this disease is its infrequency and subtlety of its early manifestations. Early diagnosis is crucial to the prognosis; effective treatment is available with copper chelators, such as penicillamine, to prevent toxic copper deposition. Dietary intake of copper should also be limited. According to the American Association for the Study of Liver Diseases, the diagnosis of Wilson's disease should be considered in patients aged 3 to 55 years with liver disease of uncertain etiology, in acute hepatic failure, and in NAFLD.⁹⁴ Treatment of asymptomatic patients prevents manifestations of the disease; however, treated symptomatic patients also often improve, sometimes dramatically.⁹³ Acute hepatic failure, end-stage cirrhosis, and failure of chelation therapy are indications for liver transplantation, which is curative.

RADIOLOGIC FINDINGS

Imaging findings of Wilson's disease are predominantly nonspecific, although more specific features have been suggested. The natural history of Wilson's disease is similar to that of other diffuse liver diseases and includes fatty infiltration, acute hepatitis, chronic active hepatitis, cirrhosis, and sequelae of portal hypertension.

Ultrasound, CT, and MRI can show heterogeneous hepatic parenchyma, contour irregularity, and macronodularity (nodules >3 mm). Ultrasound can demonstrate these macronodules, which are predominantly hypoechoic. A publication evaluating 28 patients suggests that unique imaging features of Wilson's disease, which include a normal caudate lobe-to-right hepatic lobe ratio (normal, <0.6)⁹⁵ and a perihepatic layer of fat, can be demonstrated with all three modalities.⁹⁶ HCC can occur but is reported almost exclusively in patients who have developed cirrhosis.⁹⁷

Copper has a high atomic number and can increase hepatic attenuation on CT. This can be seen diffusely or focally within hepatic nodules. This finding is not often seen, however, probably secondary to coexistent hepatic steatosis, lowering the overall hepatic density and diminishing this effect.

Copper also has a paramagnetic effect and shortens T1 relaxation time, which would be expected to result in T1 hyperintensity. Copper, however, has low magnetic susceptibility⁹⁸ and does not significantly alter the local magnetic field in comparison to other metals, such as iron and titanium. MRI signal is therefore not visibly altered in the presence of copper and cannot be used to differentiate Wilson's disease from other diffuse liver diseases. Regenerative nodules are often present and as in other forms of cirrhosis can contain iron, resulting in T1/T2 hypointensity, also nonspecific.⁹⁵

Phosphorus 31 MR spectroscopy is a technique that can be used to assess the severity of hepatic injury and provide a non-invasive baseline to assess treatment response as an alternative to percutaneous biopsy (Fig. 89-16). This technique may have limited availability and practicality.⁹⁹

Bone changes occur in up to 85% of patients and may be incidentally seen with liver imaging. These include osteomalacia, chondrocalcinosis, premature degenerative joint disease with fragmentation, cystic changes and sclerosis of subchondral bone, and anterior compression of the dorsal vertebral bodies.⁸⁷ In addition, copper accumulation in the brain results in possible cortical atrophy and mixed abnormal signal intensity within the thalami and basal ganglion.

Gaucher's Disease

CLINICAL AND PATHOLOGIC FINDINGS

Gaucher's disease is an autosomal recessive inherited disease and is the most common lysosomal storage disease caused by deficiency of the enzyme glucosylceramidase. Type I Gaucher's disease is the subtype that can involve the liver and has an incidence of 1 in 2500 births, most commonly among the Ashkenazi Jewish ethnic population. Accumulation of the enzyme's substrate, glucosylceramide, occurs within the reticuloendothelial system and, when there is hepatic involvement, within Kupffer cells. Symptoms are manifested in either childhood or early adulthood and include bone pain and fractures from bone marrow involvement and hepatosplenomegaly. The degree of liver involvement correlates with the severity of extrahepatic disease. Rarely there can be extensive replacement of the liver by Gaucher cells (lipid-laden Kupffer cells), and cirrhosis and portal hypertension can develop.^{100,101}

RADIOLOGIC FINDINGS

All imaging modalities may show hepatosplenomegaly and occasionally multiple hepatic calcifications. Bone changes are common and include modeling deformities of the lower femoral shafts ("Erlenmeyer flask" appearance), pathologic fractures, and vertebral body collapse.

In a study of 500 symptomatic patients with Gaucher's disease, 7.8% had hepatic abnormalities seen on ultrasound. Findings included hepatomegaly, fatty infiltration, heterogeneous echotexture, and focal hypoechoic or hyperechoic lesions. These focal lesions are most often the accumulation of Gaucher cells and are small and slow growing. More rapid changes should prompt evaluation for malignant disease.¹⁰² CT and MRI show similar findings, which are nonspecific; however, the presence or absence of liver abnormalities in patients with known Gaucher's disease may help triage patients who could benefit from enzyme replacement therapy.

Figure 89-16 Wilson's disease: imaging findings. **A.** A 9-year-old girl with Wilson's disease. T2-weighted axial MR image (TR/TE, 1800/90) of the liver shows numerous tiny hypointense nodules at presentation before medical treatment. Note hyperintense ascitic fluid (arrow) around edge of liver. **B.** Graph shows representative serial phosphorus 31 MR liver spectra before and after 3 and 7 months of medical treatment. Elevation in phosphomonoester (PME) resonance (long blue arrow) is concurrent with reduction in phosphodiester (PDE) resonance (short blue arrow) at presentation, followed by gradual reversal change in subsequent 3- and 7-month spectra. NTP, Nucleotide triphosphate; PI, inorganic phosphate; PCr, phosphocreatine. Sarcoidosis

CLINICAL AND PATHOLOGIC FINDINGS

Sarcoidosis is a systemic granulomatous disorder that commonly affects the liver; reported series show 24% to 79% of patients with hepatic involvement.⁶⁰⁻⁶⁵ As in the lungs and other

organs, hepatic granulomas can form. These are most often clinically unapparent, although a surrounding fibrotic and possibly immune-mediated process can occur and rarely can lead to chronic inflammation, chronic hepatitis, and cirrhosis. Three patterns of disease presentation are cholestatic liver disease with jaundice, Budd-Chiari syndrome, and cirrhosis and portal hypertension. Biopsy of the liver will reveal diffuse, small, non-caseating granulomas, usually less than 2 mm in size. The differential diagnosis for this finding on histopathologic evaluation also includes primary biliary cirrhosis. A mitochondrial antibody test can be used to differentiate these two entities; the result is negative in sarcoidosis and usually positive in primary biliary cirrhosis.¹⁰³⁻¹⁰⁸

RADIOLOGIC FINDINGS

The most prevalent CT finding (Fig. 89-17) of sarcoidosis in the liver is hepatomegaly, and hypoattenuating nodules varying in size up to 2 cm will occasionally be seen on both non-contrast and contrast-enhanced images. Because most granulomas at pathologic examination are small, imaging studies depict nodular changes in only approximately one third of affected patients. At ultrasound examination, larger granulomas can be seen as hypoechoic nodules; at MRI, when nodules are visualized, they appear hypointense on both T1-weighted and T2-weighted sequences (Fig. 89-18) compared with adjacent liver parenchyma. Associated upper abdominal lymphadenopathy, as elsewhere in the body, is often present. The

presence of hepatic nodules at imaging does not correlate with severity of pulmonary disease.¹⁰³⁻¹⁰⁸ Also unlike in pulmonary disease, resolution of imaging findings within the liver after treatment does correlate with a positive treatment response.

Figure 89-17 Sarcoidosis: CT findings. Contrast-enhanced CT scan shows hepatomegaly with innumerable small hypodense nodules. Portal adenopathy is also present (arrows). (From Warshaw DM, Lee JKT: Imaging manifestations of abdominal sarcoidosis. *AJR Am J Roentgenol* 182:15–28, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 89-18 Sarcoidosis: MR findings. **A.** Unenhanced gradient-echo T1-weighted MR image of the upper abdomen demonstrates irregularly shaped, low signal intensity nodules peripherally in the liver (arrows) and widening of the periportal tract (arrowheads). **B.** On a T2-weighted MR image of the upper abdomen, the peripheral liver nodules demonstrate increased signal intensity. Multiple hypointense nodules in the spleen create a heterogeneous appearance. The area of focal hyperintensity (arrowheads) represents gastric mucosal involvement. **C.** Ferumoxides-enhanced gradient-echo T2*-weighted MR image shows multiple hyperintense nodules scattered throughout the periphery of the liver (arrows) and a hyperintense, widened periportal tract. (From Koyama T, Ueda H, Togashi K, et al: Radiologic manifestations of sarcoidosis in various organs. *RadioGraphics* 24:87–104, 2004.)

Biliary Hamartomas

CLINICAL AND PATHOLOGIC FINDINGS

Biliary hamartomas, also known as von Meyenburg complexes, are benign malformations of the biliary tract characterized by irregular bile ducts, surrounded by fibrous stroma. These malformations are incidental findings at pathologic examination (in approximately 2.6% of the population) or imaging and almost always produce no clinical symptoms.¹⁰⁹⁻¹²¹ There are also reported associations with both polycystic liver and polycystic kidney disease. Gross pathologic specimens show small gray-white nodules. Malignant transformation is exceedingly rare, with only a few cases reported.

RADIOLOGIC FINDINGS

Biliary hamartomas are near fluid density on all modalities with some variability and appear as multiple small cysts measuring 0.5 to 1.5 cm without a capsule. Their small size helps differentiate them from simple hepatic cysts. There is no communication with the biliary tree, which can be nicely demonstrated with magnetic resonance cholangiopancreatography (MRCP). The larger lesions may be detected at imaging as multiple focal lesions, often simulating a multifocal or diffuse process. On sonographic evaluation, these lesions appear small, hypoechoic, heterogeneous, and well circumscribed. CT may show numerous small, hypoattenuating lesions on unenhanced scans that persist and may be more conspicuous as hypoattenuating lesions on postcontrast imaging. MRI (Fig. 89-19) reveals small nodules as hypointense on T1-weighted and hyperintense on T2-weighted images compared with normal parenchyma. Contrast enhancement is usually not present on CT or MRI, with the exception of some reported cases demonstrating thin peripheral enhancement.¹⁰⁹⁻¹²¹

Primary Biliary Cirrhosis

Primary biliary cirrhosis is a chronic, usually progressive liver disease characterized by inflammation and destruction of

interlobular and septal bile ducts, leading to chronic cholestasis, cirrhosis, and ultimately hepatic failure (Fig. 89-20). This is a relentless process in which the initial destructive cholangitis is followed by proliferation of atypical bile ductules, scarring, and septum formation. The etiology of this disorder is unknown, and autoimmune, genetic, and endocrine abnormalities have been postulated.¹²²⁻¹²⁷

CLINICAL AND PATHOLOGIC FINDINGS

Patients afflicted with primary biliary cirrhosis are more than 90% female and between the ages of 30 and 65 years. Pruritus and fatigue are often the first clinical symptoms, followed by jaundice months to years later. Physical findings include hepatomegaly (50%), hyperpigmentation (50%), and xanthomas

Figure 89-19 Multiple bile duct hamartomas. Magnetic resonance cholangiopancreatography image demonstrates multiple high signal intensity bile duct hamartomas. Arrowheads, Pancreatic duct.

Figure 89-20 Primary biliary cirrhosis: pathologic findings. **A.** Immunofluorescent stain shows antimitochondrial antibodies, typical of this disease. **B.** Photomicrograph of liver tissue from a 41-year-old woman with primary biliary cirrhosis with MR periportal halo sign. Stellate areas of hepatocellular parenchymal extinction (arrows) around portal triads can be seen. Larger and more variably sized regenerative nodules encircle periportal halo sign. *AJR Am J Roentgenol* 176:885-889, 2001. Reprinted with permission from the American Journal of Roentgenology.)

(25%).¹²²⁻¹²⁷ Other commonly associated autoimmune disorders are Hashimoto's thyroiditis, scleroderma, lupus, the sicca complex, celiac disease, and even other hepatic disorders, including autoimmune hepatitis and primary sclerosing cholangitis.¹²²⁻¹²⁷ Other organ systems are affected late in the disease; findings of osteomalacia with pathologic fractures, muscle wasting, palmar erythema, and clubbing are observed.

The first abnormality detected at routine checkup in an asymptomatic individual may be increased serum alkaline phosphatase and elevated cholesterol concentration. Bilirubin and transaminase levels may be normal or slightly elevated. Diagnosis of primary biliary cirrhosis is serologic and based on detection of high titers of antimitochondrial antibody and cryoproteins composed of immunoglobulins M and G (90%-95%), which are pathognomonic. The presence of antinuclear antibody (30%-50%), anti-smooth muscle antibody (30%-90%), rheumatoid factor (25%-60%), and antithyroid antibody (15%-26%) can also be seen.¹²²⁻¹²⁷ As the disease evolves, conjugated bilirubin becomes progressively elevated and may reach 30 mg/dL.¹²²⁻¹²⁷

Untreated, patient survival ranges between 7.5 and 16 years.¹²⁸ Treatment consists of anti-inflammatory agents; immunosuppressants, such as steroids, methotrexate, cyclosporine, and azathioprine; and D-penicillamine, which lowers the hepatic copper concentration and reduces circulating immune complexes and autoantibodies. Cholestyramine and rifampicin are given to treat the pruritus.¹²²⁻¹²⁷ Liver transplantation is definitive treatment in patients with advanced disease. Primary biliary cirrhosis is the third most common indication for hepatic transplantation in adults, following viral and alcohol-induced cirrhosis. Primary biliary cirrhosis can recur after transplantation within 30% within 10 years and usually with a milder course.¹²⁸

Liver biopsy is often unnecessary but can be performed when the diagnosis is equivocal. Four pathologic stages of primary biliary cirrhosis based on location of inflammatory and fibrotic changes are described. Stage 1 disease is associated with portal

inflammation; in stage 2, inflammation extends periportal, and there is bile duct proliferation; in stage 3, there is fibrosis, which extends into the septal region; and in stage 4, disease cirrhosis is present. All four stages may occur simultaneously, and the distribution may be nonuniform.¹²⁸

RADIOLOGIC FINDINGS

Endoscopic retrograde cholangiopancreatography (ERCP) is the primary radiographic technique for imaging evaluation of primary biliary cirrhosis, and cross-sectional imaging should be used to exclude extrahepatic causes of biliary obstruction and biliary cirrhosis. On ERCP, there is pruning of the peripheral bile ducts, which results in a "tree in winter" appearance. The cross-sectional imaging findings in primary biliary cirrhosis are discussed in detail in Chapter 80. Briefly, early in the course of the disease, the liver is enlarged and remains smooth in contour. Regenerative nodules later develop with hepatic atrophy, distortion, and progression to cirrhosis. Gallstones and lymphadenopathy are also frequently present. On ultrasound, the liver is heterogeneous and hyperechoic as in other forms of cirrhosis. Nodules are hyperdense on CT, isointense on T1-weighted MRI, and hypointense on T2-weighted MRI. Lacelike fibrosis surrounds the nodules and is T1 hypointense, T2 hyperintense. A reportedly specific finding (present within 43%) for primary biliary cirrhosis is the MRI "periportal halo" sign, multiple T1- and T2-weighted regions of low signal intensity measuring 5 to 10 mm surrounding small portal vein branches without mass effect in both lobes. This finding is thought to be a result of fibrosis or focal cellular depletion¹²⁹ (Fig. 89-21).

Secondary Biliary Cirrhosis

Secondary biliary cirrhosis results from long-standing partial or complete obstruction of the common bile duct

Figure 89-21 Primary biliary cirrhosis: MR findings. **A.** T1-weighted, unenhanced MR image shows numerous small regenerative nodules. **B.** T1-weighted MR image obtained 3 minutes after infusion shows conspicuous areas of low signal intensity around portal veins. **C.** T2-weighted single-shot fast spin-echo MR image reveals round areas of low signal intensity encircling portal veins.

Figure 89-22 Secondary biliary cirrhosis due to primary sclerosing cholangitis: pathologic findings. **A.** Trichrome histologic stain shows fibrosis surrounding the bile ducts. **B.** End-stage macronodular cirrhosis is seen in this specimen. Note the greenish hue of the liver.

or its major branches. Causes include postoperative strictures or choledocholithiasis often with superimposed infectious cholangitis, chronic pancreatitis, primary sclerosing cholangitis, pericholangitis of ulcerative colitis, and cystic fibrosis. Congenital atresia of the intrahepatic or extrahepatic bile ducts induces rapidly advancing periportal fibrosis in infants.

Primary sclerosing cholangitis is an idiopathic disease of chronic cholestasis of the extrahepatic and large intrahepatic bile ducts (discussed in detail in Chapters 74, 75, and 80). Similar to primary biliary cirrhosis, it is of unknown etiology with evidence for autoimmune and genetic components. Histologic grading of primary sclerosing cholangitis is similar to that of primary biliary cirrhosis (Fig. 89-22).

Cirrhosis as a result of primary sclerosing cholangitis is associated with pronounced lobulation of the liver contour, atrophy of the posterior right lobe and left lateral segment of the left lobe, and hypertrophy of the caudate lobe. Atrophy of the lateral segment of the left lobe is distinctive (Fig. 89-23) because hypertrophy rather than atrophy of the lateral segment of the left lobe is typical in most other forms of cirrhosis. The caudate lobe may have a higher attenuation than the remainder of the liver on noncontrast scans, producing a pseudotumor appearance. Enlarged lymph nodes in the lesser omentum are also common.¹²⁹⁻¹³⁷

On MRI (Fig. 89-24), peripheral wedge-shaped zones of hyperintense signal can be seen on T2-weighted images. These triangular areas range in size from 1 to 5 cm. On T1-weighted images, areas of increased signal intensity in the liver that do not correspond to fat may be seen. After the administration of contrast material, areas of increased enhancement that are patchy or segmental are frequently seen. These areas often remain mildly or markedly hyperintense on delayed images. Primary sclerosing cholangitis often produces large regenerative nodules that may cause obstruction of bile ducts and ultimately segmental atrophy of the peripheral liver.¹²⁹⁻¹³⁷

Clinical history is important in differentiating between causes of secondary biliary cirrhosis. Evidence of cholecystectomy, chronic pancreatitis, or biliary stones may be helpful. The treatment approach is the same as in primary biliary cirrhosis for end-stage disease and is curative only with liver transplantation.

Figure 89-23 Secondary biliary cirrhosis due to primary sclerosing cholangitis: CT findings. Advanced cirrhotic changes are present with a markedly lobulated liver, enlargement of the caudate lobe (C), and widening of the fissures. There is atrophy of the lateral segment (LS) of the left lobe, which is a key differentiating feature from alcoholic and posthepatic cirrhosis. Note the splenomegaly and retroperitoneal varices (arrow).

Acquired Immunodeficiency Syndrome

CLINICAL FINDINGS

With improved survival of AIDS patients since the introduction of antiretroviral therapy, hepatic manifestations of AIDS have increased in prevalence and are now the leading cause of death (14%-18%). The hepatobiliary disease profile affecting AIDS patients, which includes infection, malignant neoplasm, autoimmune abnormalities, and drug toxicity, has also changed.¹³⁸⁻¹⁴¹

A long list of opportunistic infections including viral, bacterial, and fungal that can be a result of the immunocompromised state of HIV infection and AIDS can cause primary or disseminated infection of the liver. Before antiretroviral therapy, the most common infectious organisms were cytomegalovirus and

Figure 89-24 Secondary biliary cirrhosis due to primary sclerosing cholangitis: CT findings. **A.** T2-weighted, single-shot, fat-suppressed image shows a very lobulated liver with caudate lobe enlargement and atrophy of the lateral segment of the left lobe. In a different patient, early (**B**) and delayed (**C**) T1-weighted images after the administration of gadolinium show peripheral areas of fibrosis, with contrast accretion on the delayed image (arrows).

non-tuberculosis *Mycobacterium*. Although these and other infectious agents (Table 89-2) continue to affect AIDS patients, currently the most clinically significant coinfection with HIV infection is viral hepatitis. Concurrent hepatitis B is present in 25% and hepatitis C in 10% of HIV-infected patients because of a similar route of transmission. The increased life span of AIDS patients receiving antiretroviral therapy can result in adequate time for chronic viral hepatitis to progress to cirrhosis. This progression is also accelerated in the setting of coinfection with HIV infection in comparison to patients with viral hepatitis alone. Cirrhosis and its comorbidities, including HCC, are now a significant cause of death in the AIDS population. *Mycobacterium avium* complex and cytomegalovirus remain the most common hepatic infections in AIDS. Interestingly, *Pneumocystis jiroveci* can preferentially involve the liver when inhaled prophylactics protect the lungs. Another entity known as bacillary peliosis hepatitis, a rare process in which blood-filled cavities form in the liver, replacing the parenchyma, is associated with *Bartonella* infection.¹³⁸⁻¹⁴¹

AIDS patients are at increased risk for malignant disease including AIDS-related lymphoma and Kaposi's sarcoma. Non-Hodgkin's lymphoma involves the liver in 33% of cases and can be manifested nonspecifically with pain or jaundice and with

nonspecific increase in liver function test results. Kaposi's sarcoma involves the liver in 9% of cases and clinically is most often asymptomatic. HCC, as mentioned before, and other malignant neoplasms, such as anal and cervical cancers, are other important malignant neoplasms to consider in the AIDS patient.

Drug therapies commonly used to treat AIDS patients, including antimycobacterial agents, acyclovir, and sulfonamides, can unfortunately be hepatotoxic.¹⁴¹ This can be manifested with mild symptoms and elevation of liver function test results to fulminant hepatic failure. The hepatotoxic effect of these drugs is increased when there is concurrent viral hepatitis and HIV infection. The mechanisms for hepatic damage include direct drug toxicity, hypersensitivity reactions, mitochondrial toxicity, and immune reconstitution inflammatory syndrome.

Biliary disease in AIDS patients encompasses AIDS cholangiopathy and acalculous cholecystitis, both attributed to infectious causes, most commonly cryptosporidium and cytomegalovirus. Other infectious agents as well as autoimmune diseases as mentioned before can also affect the biliary system. AIDS cholangiopathy results in biliary obstruction, which can clinically be manifested with right upper quadrant pain, fever, nausea, and vomiting. There is marked elevation in alkaline phosphatase, with less increase in bilirubin and normal or slight increase in liver function test results. This is manifested most commonly in patients with low CD4 count and therefore is less common since implementation of antiretroviral therapy, which is also the preferred therapy. Cholecystectomy is preferred in cases of acalculous cholecystitis.¹³⁸⁻¹⁴¹

Other causes of hepatobiliary disease in AIDS patients include NAFLD, alcoholic hepatitis, and autoimmune diseases such as autoimmune hepatitis, primary biliary cirrhosis, and primary sclerosing cholangitis.

PATHOLOGIC FINDINGS

Therapeutic decisions seldom require liver biopsy, nor does biopsy significantly correlate with improved survival. Liver biopsy should be reserved for patients with unexplained fever, patients with an elevated serum alkaline phosphatase level, and those with focal mass lesions seen on imaging studies. The list of opportunistic infections in AIDS patients is long (see [Table 89-2](#)). Organisms can be isolated from biopsy specimens for tailored therapy.

AIDS hepatic disease is histologically nonspecific. Macrovesicular steatosis and portal inflammation represent the most common findings. Hepatic granulomas have been reported in 16% to 100% of biopsy and autopsy specimens. These granulomas are most frequently associated with mycobacterial infection, usually *Mycobacterium avium-intracellulare*. In AIDS cholangiopathy, recovered infectious agents include cryptosporidium and cytomegalovirus. On pathologic examination, there is periductal inflammation. Targeted biopsy of a hepatic mass may be used to diagnose Kaposi's sarcoma or AIDS-related lymphoma.¹³⁸⁻¹⁴¹

RADIOLOGIC FINDINGS

Ultrasound

On ultrasound studies, hepatic parenchymal abnormalities in AIDS patients include hyperechoic parenchyma (45.5%), hepatomegaly (41%), and focal masses (9%). Hepatic steatosis and

granulomatous hepatitis are responsible for increased echogenicity of the liver.^{12,141} It is postulated that the tiny aggregates of histiocytes found in granulomas act as multiple reflective interfaces that produce the hyperechoic pattern. Metastatic Kaposi's sarcoma, lymphoma, pyogenic abscess, fungal or mycobacterial abscess, and preexisting benign lesions such as hemangiomas can also be seen sonographically as focal masses.^{28,141}

On ultrasound, AIDS cholangiopathy is manifested with periportal hyperechoic and hypoechoic regions associated with mural thickening of the gallbladder, cystic duct, and bile ducts and can simulate primary sclerosing cholangitis. Acalculous cholecystitis is manifested with gallbladder wall thickening and distention without cholelithiasis and can be manifested acutely with a sonographic Murphy sign, pain, and fever. The biliary manifestations of AIDS are also illustrated in Chapter 80.

Kaposi's sarcoma is uncommonly seen on ultrasound; however, when present, these lesions may appear as small (5- to 12-mm) hyperechoic nodules with associated dense periportal bands. The presence of hepatomegaly does not predict Kaposi's sarcoma involvement because the liver is commonly enlarged in patients with AIDS or AIDS-related complex even when there is no specific pathologic process.^{28,47,141}

Hepatic lymphoma with ultrasound is usually hypoechoic compared with the normal liver parenchyma and may be anechoic and septate, mimicking a fluid collection. Associated adenopathy in the porta hepatis and retroperitoneum can be present but is nonspecific; it may also be present as a result of AIDS alone, chronic hepatitis, infection, or other neoplasm.^{28,47,141}

Computed Tomography

On CT scans, patients with AIDS generally demonstrate hepatomegaly that is often associated with focal or diffuse fatty infiltration. Patients with long-standing hepatitis and postnecrotic change may also present with cirrhosis. Periportal lymphedema seen as low attenuation surrounding the large portal branches is also common and reflects lymphadenitis, hepatitis, or malnutrition.¹⁴¹

Cirrhosis can occur in an accelerated fashion when both HIV infection and viral hepatitis are present; they are indistinguishable from other causes of cirrhosis at imaging, other than possibly by a more rapidly progressive disease course. Screening for HCC with multiphase contrast-enhanced CT is also necessary.

Lymphoma is particularly aggressive in AIDS patients, and hepatic involvement is manifested on CT scans by focal hypodense lesions because of the high cellular content. CT abnormalities are more commonly found in affected livers in AIDS-associated lymphoma than in those with lymphoma and without AIDS.

Parenchymal calcifications in the liver, spleen, lymph nodes, and kidneys can be seen in patients with healed disseminated *P. jiroveci* infection. Kaposi's sarcoma can involve the liver in AIDS, but the lesions are usually not seen on CT. When present, they appear as small low-attenuation masses often located near the portal triads, which may simulate the appearance of intrahepatic bile ducts or fungal microabscesses. Masses in Kaposi's sarcoma show enhancement on delayed scans, helping to differentiate them from cystic lesions.¹³⁸⁻¹⁴¹

AIDS cholangiopathy is manifested with mural thickening of the gallbladder; gallbladder distention; and intrahepatic and extrahepatic biliary strictures, irregularity, and dilation.¹⁴¹

Endoscopic Retrograde Cholangiopancreatography

ERCP is useful in demonstrating the findings of AIDS cholangiopathy. Irregularity of the intrahepatic and extrahepatic bile duct walls with intervening strictures and dilation simulating primary sclerosing cholangitis is the cholangiographic corollary of biliary abnormalities seen with ultrasound and CT. Specific findings of ampullary stenosis, common bile duct enlargement, and ulcerations of the common bile duct mucosa combined with intrahepatic strictures can help differentiate these entities. ERCP also has the advantage of offering therapeutic relief in these patients by performance of a papillary sphincterotomy.¹³⁸

MRI and MRCP

MRI is most useful to assess AIDS cholangiopathy and demonstrates the dilated and irregular bile ducts, which are hypointense on T1-weighted and hyperintense on T2-weighted imaging. Fat-suppressed T1-weighted dynamic images after the administration of contrast material can demonstrate enhancement along the bile ducts as a result of periportal inflammation. MRI with contrast enhancement is also useful in demonstrating hepatic abscesses, whether bacterial or fungal, and is more sensitive than ultrasound and CT. MRI can also help differentiate abscesses from malignant disease. Another advantage of MRI is the large field of view permitting assessment for concurrent disease of other abdominal organs, particularly the spleen. Cirrhosis and other nonspecific findings in AIDS-related hepatic disease, including lymphadenopathy, focal masses, and fatty infiltration, can also be seen at MRI with high sensitivity.

MRCP, a heavily T2-weighted, high-resolution sequence that is similar to ERCP, can noninvasively demonstrate enlargement and focal irregularities from strictures of the intrahepatic and extrahepatic biliary tree. These appear hyperintense because of the fluid content and may be subtracted from the surrounding

hepatic parenchyma and other background with the use of a long echo time. Enlargement of the common bile duct from ampullary stenosis can also readily be seen.¹³⁸⁻¹⁴¹

Cirrhosis

EPIDEMIOLOGY

Cirrhosis is the end response of the liver to chronic inflammation complicated by parenchymal necrosis and fibrosis. Nodular regeneration also occurs; as a result, there is disorganization of the hepatic lobular and vascular architecture coupled with deteriorating hepatic function. Cirrhosis can result from a variety of causes. The most common worldwide is hepatitis B, closely followed by alcohol abuse, NAFLD, and hepatitis C.

Cirrhosis is one of the leading causes of death in the Western world and was the ninth leading cause in the United States in 2012. Age-adjusted mortality is 2.3 times higher in males than in females and 1.7 times higher in black than in white persons. The mortality rate from cirrhosis has also shown a major increase in the United States during the past 25 years; it is a significant cause of premature death, the fifth leading cause of death in the 45- to 64-year age group, and the third leading cause of death for men 34 to 54 years of age. One third of deaths related to cirrhosis are consequent to hemorrhage, usually from esophageal varices.¹⁴²⁻¹⁴⁵

PATHOPHYSIOLOGY

Although no completely satisfactory scheme for the classification of cirrhosis (Fig. 89-25) has been developed, the disorder has traditionally been divided into several categories: (1) micronodular cirrhosis, in which equal-sized nodules up to 3 mm in diameter involve every lobule; (2) macronodular (postnecrotic) cirrhosis, characterized by variable-sized nodules (3 mm to 3 cm) that are focal and do not involve every lobule;

Figure 89-25 Cirrhosis: pathologic findings.

A. Photomicrograph shows a regenerative nodule (RN) with surrounding fibrosis, the key pathologic finding in cirrhosis. This patient had hepatitis C cirrhosis. **B.** Micronodular cirrhosis is evident in this specimen image of a patient with alcoholic cirrhosis. **C.** Larger nodules are present in this specimen image of macronodular cirrhosis.

and (3) mixed cirrhosis. Alcoholic cirrhosis is associated with the micronodular pattern. Viral hepatitis is associated with the macronodular pattern. Other causes include primary and secondary biliary cirrhosis and hemochromatosis.¹⁴²⁻¹⁴⁵ A more complete listing of the causes of cirrhosis can be found in Table 89-3.

On pathologic examination, all forms of cirrhosis share the following characteristics: (1) the entire parenchymal architecture is disorganized by interconnecting fibrous scars formed in response to hepatocyte injury and death; (2) the fibrosis may appear as delicate portal-central or portal-portal bands or constitute broad scars replacing multiple adjacent lobules; (3) the micronodules or macronodules are created by regenerative activity with the intervening network of scars; and (4) the vascular architecture of the liver is reorganized by the parenchymal damage and scarring with formation of abnormal arteriovenous interconnections.

Regenerative nodules have been further classified as siderotic or nonsiderotic, with a greater tendency for siderotic nodules to undergo malignant transformation. The increased incidence of HCC in patients with cirrhosis has been shown in part to be a progression of dysplasia within regenerative nodules, with the precursor to HCC being dysplastic nodules.¹⁴²⁻¹⁴⁵ HCC may be seen in patients infected with hepatitis B virus without development of cirrhosis. The presence of dysplastic nodules confers an increased risk of HCC through dedifferentiation not only of the dysplastic nodule itself but also in other regions of the liver. Longitudinal studies indicate that dysplastic nodules remain stable in size unless there is progression to HCC.^{146,147} Dysplastic nodules have been reported to occur in 15% to 25% of patients with cirrhosis (usually less than 10 per liver) on the basis of histopathology data,^{146,147} although typically not all dysplastic nodules are identified at imaging.

Life-threatening complications of cirrhosis are related to decline in hepatic function and development of portal hypertension.¹⁴²⁻¹⁴⁵ Ascites is the most common complication of cirrhosis and is associated with nearly 50% of deaths. Variceal hemorrhage in patients with ascites accounts for nearly 25% of deaths; 10% are due to renal failure resulting from the hepatorenal syndrome, 5% result from spontaneous bacterial peritonitis in patients with massive ascites, and 10% are due to the complications of interventions for ascites.¹⁴²⁻¹⁴⁵

A third potentially life-threatening sequela of cirrhosis is the development of HCC. Its incidence varies with the underlying

etiology, with an increased incidence in cirrhosis caused by alcoholism and a 2.5-fold greater occurrence in cirrhosis with hepatitis B surface antigen positivity. HCC has also been reported in patients with various other types of cirrhosis, including primary biliary cirrhosis, NASH, Wilson's disease, and hemochromatosis.¹⁴²⁻¹⁴⁵

PORTAL HYPERTENSION

The fibrosis of the liver that occurs with cirrhosis can result in dramatic changes in the hepatic circulation. The scarred parenchyma causes an increase in intrahepatic vascular resistance that decreases portal venous liver perfusion. This leads to increased pressure within the portal system, normally between 5 and 10 mm Hg; portal hypertension is defined as a portal venous pressure of more than 10 mm Hg.

The hepatic artery, with a higher systemic pressure and muscle support of its wall, increases its flow and contribution of blood supply to the liver, allowing partial compensation. In addition, capillarization of the sinusoids is observed in the form of endothelial defenestration, deposition of collagen in the extravascular spaces of Disse, and formation of basal laminae. The transit time of large and small molecules, including contrast material, is significantly affected by the sinusoidal capillarization.¹⁴⁵

Portal hypertension may develop in a variety of clinical conditions but is most often secondary to cirrhosis. The causes of portal hypertension (Table 89-4) have been classically divided

TABLE 89-3 Etiology of Cirrhosis

Alcoholic cirrhosis (60%-70%)
Postnecrotic: viral hepatitis (10%)
Biliary cirrhosis: primary and secondary (5%-10%)
Pigment cirrhosis: hemochromatosis (5%)
Cardiac failure
Constrictive pericarditis
Hepatic vein obstruction
Malnutrition
Hereditary: Wilson's disease, α_1 -antitrypsin deficiency, galactosemia, tyrosinemia, hereditary tetany, hereditary fructose intolerance, type IV glycogen storage disease, Osler-Weber-Rendu syndrome
Drug induced: methotrexate, oxyphenisatin, α -methyl dopa, nitrofurantoin, isoniazid, mithramycin, 6-mercaptopurine, azathioprine

into three major groups according to the level of obstruction: presinusoidal, postsinusoidal, and sinusoidal (intrahepatic). In most of these disorders, increased resistance to portal flow is found. In several diseases, there is increased flow into the portal system, so-called hyperkinetic portal hypertension.

Cirrhosis is the most common cause of sinusoidal portal hypertension. It occurs secondary to the mechanical effect of the regenerative nodules and scar tissue that distort the hepatic vascular tree and impedes hepatic drainage and ultimately produces backpressure in the portal system. This alteration in the microcirculatory route leads to portal hypertension.

Presinusoidal obstruction can be caused by schistosomiasis, the leading cause of portal hypertension worldwide. The ova of the schistosomes travel through the mesenteric venous circulation into the portal venous system and implant on small portal radicles within the liver, where they induce inflammation and granuloma formation, resulting in destruction of the portal venules. Other major presinusoidal causes of portal hypertension are portal or splenic vein thrombus, primary biliary cirrhosis, sarcoidosis, myeloproliferative disease, and congenital hepatic fibrosis.^{145,148}

Posthepatic obstruction occurs in patients with veno-occlusive disease (Budd-Chiari syndrome), right-sided heart failure, and constrictive pericarditis (discussed in Chapter 90).

Increased portal flow is an infrequent cause of portal hypertension and is usually secondary to either congenital (hereditary hemorrhagic telangiectasia) or acquired (post-traumatic or aneurysm rupture) arteriovenous fistulas. Hyperkinetic portal hypertension involves increased portal flow without fistulas, splenomegaly, and increased flow in the splenic artery and vein.

Varices

With increasing portal hypertension, portal venous blood flow seeks a pathway of less resistance and can change direction, resulting in the formation of portosystemic collateral vessels known as varices. These can be classified into two groups: varices that drain toward the superior vena cava and varices that drain toward the inferior vena cava.¹⁴⁸

Varices That Drain into the Superior Vena Cava. The left gastric (coronary) vein is the most common visible varix in portal hypertension. It is located in the gastrohepatic ligament and drains into the superior vena cava. The normal left gastric vein drains both the anterior and posterior surfaces of the stomach, and it ascends the lesser curvature within the lesser omentum to the esophageal hiatus, where it anastomoses with the esophageal veins. The left gastric vein divides into anterior branches draining to the esophageal veins and posterior branches draining to the paraesophageal veins. Left gastric varices typically are accompanied by esophageal or paraesophageal varices. Esophageal and paraesophageal varices usually drain into the azygos-hemiazygos venous system but may also enter the subclavian-brachiocephalic system through the left pericardiophrenic vein or the inferior vena cava through the inferior phrenic vein. When the left gastric vein is larger than 5 to 6 mm in diameter, portal hypertension should be considered. A left gastric vein larger than 7 mm in diameter is associated with a portohepatic gradient greater than 10 mm Hg.¹⁴⁸

Short gastric veins are present in the gastrosplenic ligament and drain the gastric fundus. They communicate with the splenic vein or one of its large tributaries along the greater

curvature of the stomach. These vessels can be dilated in isolation with splenic vein thrombosis.¹⁴⁸

Varices That Drain into the Inferior Vena Cava. The splenic vein and left and short gastric veins communicate with the left renal vein through the splenorenal and gastrosplenic ligaments, respectively. Reversal of blood flow in these veins from portal hypertension can cause preferential drainage into the left renal vein and a splenorenal or gastrosplenic shunt. Normally, four or five short gastric veins drain the gastric fundus and the left part of the greater curvature, traversing the gastrosplenic ligament to reach the splenic vein. Short gastric veins should be smaller than 5 mm in diameter. Gastrosplenic and splenorenal shunts are seen as varices in the region of the splenic and left renal hilum that drain into an enlarged left renal vein. This may cause fusiform dilation of the inferior vena cava at the level of the left renal vein.¹⁴⁸

Small veins normally found in the ligamentum teres and falciform ligament can enlarge and form paraumbilical varices arising from the left portal vein. These vessels may also course through the medial segment of the liver rather than the ligamentum teres. Paraumbilical varices can anastomose either with the superior epigastric or internal thoracic veins and drain into the superior vena cava or with the inferior epigastric vein and then drain into the inferior vena cava through the external iliac vein. Varices in the anterior abdominal wall surrounding the umbilicus produce the “Medusa’s head” appearance.¹⁴⁸

Collateral vessels may also arise from the superior and inferior mesenteric veins within the subperitoneal space of the small bowel mesentery. These usually drain into the retroperitoneal or pelvic veins. A retroperitoneal shunt may develop between the mesenteric vessels and the renal vein or inferior vena cava. Veins of Retzius are communications between the inferior vena cava and intestinal or retroperitoneal tributaries of the superior or inferior mesenteric veins and systemic veins.¹⁴⁸

The intrahepatic portal veins can form collateral pathways with hepatic venous branches or direct communication with the left gastric vein. There is a loose collateral plexus over the hepatic surface, and it is sometimes widely distributed over the parietal peritoneum with branches piercing the diaphragm to join pericardial, pleural, and pulmonary veins, the so-called pleuropericardial collaterals. The intercostal veins may also dilate and help drain hepatofugal blood flow through the azygos-hemiazygos system.¹⁴⁸

GENERAL RADIOLOGIC FINDINGS: CIRRHOSIS

Liver Morphology

Many of the morphologic changes that occur in cirrhosis can be appreciated with multiple modalities, including ultrasound, CT, and MRI. These include gross changes in the hepatic size, vascular changes, and extrahepatic findings (Table 89-5).

Changes in the hepatic parenchyma in cirrhosis occur in a predictable pattern with asymmetric atrophy of the right lobe and medial left lobe and preservation or increase in size of the lateral left lobe and caudate lobe. These changes can often be qualitatively observed but can also be demonstrated quantitatively with comparative measurements. The normal size ratio of the right lobe to the left lobe is 1.44. In cirrhosis, this ratio decreases to less than 1.3, most prominent in viral hepatitis-associated cirrhosis (mean, 1.17) and less

TABLE 89-5 Cirrhosis: Morphologic Features

Nodular hepatic contour
Enlarged caudate lobe
Enlarged lateral segment of left lobe
Atrophy of the right and quadrate lobes
Prominence of the fissures and porta hepatis
Portal hypertension: varices, ascites, splenomegaly
Fatty infiltration
Colonic interposition
Altered gallbladder angle
Increased density of mesenteric fat
Regenerative nodules
Intrahepatic arterial-portal fistulas
Fibrosis (focal confluent or lacy network surrounding nodules)

pronounced in non-hepatitis-related cirrhosis (mean, 1.25). A ratio of 1.40 reportedly excludes cirrhosis in 100% of cases; a ratio of 1.35 has 90% sensitivity, 82% specificity, and 81% accuracy; a ratio of 1.3 has 74% sensitivity, 100% specificity, and 93% accuracy.¹⁴⁸⁻¹⁵⁵

Hepatic segment IV also undergoes atrophy in patients with cirrhosis. Compared with a normal mean diameter of 43 ± 8 mm (standard deviation), the mean diameter of segment IV is 28 ± 9 mm in patients with cirrhosis. The cause or severity of cirrhosis had no influence on the size of segment IV.¹⁵⁴ Lafortune and colleagues¹⁵⁴ found that measurement at ultrasound of the transverse diameter of segment IV had a sensitivity of 74% for the diagnosis of cirrhosis, with a specificity of 100%.¹⁵⁴ The transverse diameter was obtained from a measurement between the left wall of the gallbladder and the ascending portion of the left portal vein at the point where it gives rise to the segment IV branch. These results were obtained by use of a lower limit of normal diameter of 30 mm, with atrophy below that indicative of cirrhosis.

Measurements of the ratio of the caudate lobe size to that of the right lobe have been reported to be accurate in diagnosing the presence or absence of cirrhosis. To determine the caudate lobe-to-right lobe ratio, the caudate lobe is measured transversely from its most medial aspect to the right lateral wall of the main portal vein, just caudal to its bifurcation. The right lobe is measured from the same portion of the main portal vein to the right lateral margin of the liver. If the caudate lobe-to-right lobe ratio exceeds 0.65, the diagnosis of cirrhosis can be made with 96% confidence. By use of this sole criterion, the diagnosis can be made with a sensitivity of 84%, specificity of 100%, and accuracy of 94%. The normal caudate lobe-to-right lobe ratio is 0.37, and the mean ratio in cirrhotic livers is 0.83. An alternative measurement uses the right portal venous bifurcation rather than the bifurcation of the main portal vein to mark the lateral boundary of the hypertrophied caudate lobe and central liver from the atrophied right lobe.¹⁵⁶

The gallbladder and interlobar fissure also undergo counter-clockwise rotation in patients with cirrhotic liver morphology. These topographic alterations may be quantified by measuring the gallbladder angle. This angle is determined by drawing a line through the interlobar fissure, gallbladder neck, or medial aspect of the anterior segment of the right hepatic lobe (whichever is visible) and the inferior vena cava. Another line is drawn coronally through the inferior vena cava parallel to the patient's back. The gallbladder angle subtended by these lines is a useful marker of gallbladder position. In normal patients, the angle is

46 degrees, but in cirrhosis, the angle is reduced to 35 degrees. Thus, the gallbladder becomes a more lateral and superficial structure in cirrhosis, prone to inadvertent injury during "blind" liver biopsy, surgery, and percutaneous transhepatic procedures.¹⁵⁶⁻¹⁵⁹

The alterations in segmental hepatic anatomy described previously produce profound changes in the topography of the right upper quadrant. Colonic interposition between the liver and the anterior lateral abdominal wall or diaphragm is seen in 25% of cirrhotic patients as opposed to 3% of control subjects on CT scans.¹⁵⁶⁻¹⁵⁹ Although these measurements do reflect the underlying morphologic changes and are documented in peer-reviewed literature, they are infrequently needed in clinical practice to diagnose cirrhosis.¹⁵⁶⁻¹⁵⁹

A vascular corollary of the changes in the segmental morphology of the liver has been described. Normally, the diameter of the right portal vein is greater than that of the left portal vein because the right hepatic lobe is larger than the left lobe. When the lateral segment of the left lobe hypertrophies and the right lobe atrophies, the left portal vein diameter becomes equal to or greater than the right portal vein diameter. The sensitivity and specificity of this finding are 85% and 88%, respectively, for alcoholics without recanalization of the umbilical vein.¹⁴²⁻¹⁵⁸

The cirrhotic liver is defined by the presence of both nodules and fibrosis. A spectrum of nodules (Figs. 89-26 and 89-27) ranging from benign regenerative nodules to HCC can be visualized on pathologic examination and cross-sectional imaging.¹⁶⁰⁻¹⁷⁰ Regenerative nodules are a benign process that is the liver's response to cellular injury and attempt at parenchymal repair. Dysplastic nodules are thought to be an evolutionary process from a dominant large regenerative nodule associated with increased iron content, the siderotic nodule. These nodules are at risk for malignant transformation.

At the time of transplantation, approximately 20% of patients with hepatitis B or C and 10% of patients with alcohol-induced cirrhosis will harbor an occult HCC. For detection, noncontrast, late arterial, portal venous, and delayed phase imaging sequences after administration of a large bolus of contrast material are important. Even with optimum technique, 35% to 40% of lesions will not be detected.¹⁶⁰⁻¹⁷⁰ The cirrhotic liver also demonstrates pseudotumors, such as focal confluent fibrosis, and vascular anomalies, including arteriportal shunts, small arteriovenous malformations, and hemangiomas.¹⁶⁰⁻¹⁷⁰

The fibrosis seen in cirrhosis is usually a diffuse, lacy process that surrounds and increases the conspicuity of regenerative nodules throughout the liver parenchyma. In patients with advanced cirrhosis, approximately 30% will develop collapse of normal hepatic architecture and replacement of liver parenchyma with massive, confluent regions of fibrosis, termed focal confluent fibrosis (see Fig. 89-27). This can simulate a mass. Fortunately, associated morphologic changes are often present that allow characterization of focal confluent fibrosis. These lesions most commonly affect the anterior segment of the right lobe and the medial segment of the left lobe, usually with a wedge-shaped appearance radiating from the porta hepatis. Another key differentiating feature is associated focal capsular retraction over the abnormal region due to atrophy in the fibrotic region. Most untreated tumors, by comparison, cause a bulge in the overlying liver contour. When focal confluent fibrosis has an atypical appearance or location, it can be difficult to differentiate from tumor.¹⁵⁶⁻¹⁵⁹ Contrast enhancement of focal

Figure 89-26 Hepatocellular nodules in cirrhosis: MR features. **A.** Stepwise pathway of carcinogenesis for hepatocellular carcinoma (HCC) in cirrhosis. One or more regenerative nodules may show signs of atypia and change into dysplastic nodules. Atypia indicates a number of changes in the shape and size of the nuclei and the cytoplasm of the hepatocytes. These changes often result in an increased number of cells (increased cellularity), which may be present in groups of small cells (small cell dysplasia) or large cells (large cell dysplasia). Atypia within dysplastic nodules can progress further and give rise to small and large HCCs. In addition to the cellular changes, the hepatic parenchymal structure will often be distorted in HCC. **B.** Opposed-phase MR image shows hyperintense dysplastic nodule in the right lobe of the liver (arrow). Precontrast (**C**), postcontrast (**D**), and subtraction (**E**) images show enhancement of a dysplastic nodule (arrow) that had a subfocus of HCC pathologically. **F.** Small HCC (red arrow) is present within a cirrhotic liver showing a nodular hepatic contour, right lobe notch (broken yellow arrow), enlarged lateral segment (LS) of the left lobe, and superficial gallbladder (solid yellow arrow). (A from Hussain SM, Zondervan PE, Ijzermans JN, et al: Benign versus malignant nodules: MR imaging findings with pathologic correlation. *RadioGraphics* 22:1023–1039, 2002.)

hepatic fibrosis with either CT or MRI most commonly demonstrates delayed enhancement only, a key differentiation from a typical HCC.

Etiology of Specific Findings

Although the imaging findings for cirrhosis are most often non-specific in regard to the underlying etiology, some disease-specific alterations can be observed.

The volume of the caudate lobe is often significantly larger in alcoholic cirrhosis than in other causes of cirrhosis, including viral hepatitis. In addition, a notch in the right posterior hepatic lobe is more commonly seen in alcoholic cirrhosis. Regenerative nodules are significantly greater in size in hepatitis B-related cirrhosis than in alcoholic cirrhosis.¹⁷¹

Patients with biliary cirrhosis (see Fig. 89-21B), particularly secondary to chronic changes from sclerosing cholangitis (see

Figure 89-27 Confluent hepatic fibrosis: MR features. **A.** T1-weighted image shows wedge-shaped hypointense regions (arrows) along the anterior aspect of the right lobe and the medial segment of the left lobe. **B.** On the T2-weighted image, the areas of fibrosis are mildly hyperintense (arrows). This patient has ascites. **C.** Contrast-enhanced, T1-weighted MR image in a different patient shows the classic location of capsular retraction in confluent hepatic fibrosis (arrow). Note the hypertrophy of the caudate lobe (C) and lateral segment (LS) of the left lobe.

Figs. 89-23 and 89-24), in addition to the marked atrophy of the right lobe often characteristically have marked atrophy of the lateral segment of the liver. These changes, coupled with marked caudate lobe hypertrophy, result in a squared or rounded appearance to the liver. The atrophy of the more distal parts of the liver to a greater degree in these patients is thought to be due to the effects of chronic biliary obstruction. In addition, zones of focal fibrosis in these patients can appear as peripheral bands of low attenuation.

Extrahepatic Findings

Mesenteric, omental, and retroperitoneal edema can be seen in patients with cirrhosis and portal hypertension. The increased hydrostatic pressure within the mesenteric veins causes fluid to seep into the mesentery. Liver dysfunction also produces a state of water overload due to hypoalbuminemia and decreased aldosterone catabolism. These features also play a role in the development of mesenteric edema, ascites, pleural effusion, and subcutaneous edema. With increasing severity, mesenteric edema can develop a more diffuse distribution and masslike appearance associated with recruitment of omental and retroperitoneal sites. The degree of edema correlates with other findings of severe ascites, subcutaneous edema, pleural effusions, and low mean serum albumin concentration.¹⁴²⁻¹⁵⁸

Siderotic nodules, or Gamna-Gandy bodies, may rarely be identified as masses in the spleen.¹⁵³ Siderotic nodules are seen in patients with portal hypertension and are caused by focal hemorrhage into the spleen. The nodules are composed of fibrous tissue encrusted with hemosiderin and calcium. Presumably, the fibrous tissue and calcium account for these echogenic splenic masses. The incidence of gallstones is also increased in patients with cirrhosis regardless of etiology or gender. A

number of mechanisms make stones more prevalent in the cirrhotic population. Ingestion of alcohol may cause spasm of the sphincter of Oddi and edema of the papilla of Vater, thus interfering with bile duct and gallbladder emptying. Bile stasis and calculus formation may result from poor food intake and excessive alcohol consumption. Indeed, ascites, encephalopathy, and varices are more common in cirrhotic patients with stones than in those without stones. Chronic hemolysis is perhaps the most significant factor in pigment stone formation. Hypersplenism is another major contributing factor. Because of functional damage to the liver, cholesterol stones are uncommon in cirrhotic patients.¹⁴²⁻¹⁵⁸

As with hepatitis, the chronic inflammation present in cirrhosis results in enlargement of abdominal lymph nodes in multiple upper abdominal locations. Such enlarged nodes range in size up to 4 cm in maximal diameter and can be found in patients with cirrhosis from all causes. Although they are most common in patients with primary biliary cirrhosis and primary sclerosing cholangitis, enlarged nodes have been reported with high frequency in patients with alcoholic cirrhosis (37%) and hepatitis B or C (45%-49%). The affected lymph node chains reported include (in order of frequency of involvement) the portacaval space, porta hepatis and hepatoduodenal ligament, gastrohepatic ligament, cardiophrenic angle, and celiac axis as well as other lesser, more remote abdominal chains.¹⁵⁶⁻¹⁵⁹

ULTRASOUND: CIRRHOSIS

Liver Morphology

The sonographic features of fibrosis and fatty infiltration can also overlap significantly. Both demonstrate decreased beam penetration of the hepatic parenchyma, decreased

conspicuity of intrahepatic vessels, and increased parenchymal echogenicity¹⁴⁸⁻¹⁵⁵ (see Table 93-11). Some authors have shown that the attenuation of sound can be normal in cirrhotic patients without fatty deposition. Cirrhosis should be suspected if on ultrasound there are alterations in liver size as detailed before, nodularity of the liver surface, accentuation of the fissures, heterogeneity and coarsening of the hepatic architecture, nodules, or signs of portal hypertension (Fig. 89-28). Specifically, contour nodularity of the undersurface of the liver has a high sensitivity of 86% versus 53% along the superior surface.¹⁷²

The reported sensitivity of ultrasound in the diagnosis of cirrhosis based on hepatic architecture varies between 65% and 95%.¹⁴⁸⁻¹⁵⁵ Although ultrasound has up to a 98% positive predictive value in the diagnosis of diffuse parenchymal disease, it cannot reliably differentiate the underlying etiology. Irregularity of the liver surface has been suggested as a fairly sensitive sign (88%) of cirrhosis. It is detected by use of a high-frequency (9 MHz) linear probe.¹⁴⁸⁻¹⁵⁵ Surface nodularity correlates pathologically with sinusoidal obstruction to portal flow and the development of portal hypertension. It has a higher correlation with severe fibrosis or cirrhosis on histopathologic evaluation than with caudate lobe hypertrophy or hepatic venous flow abnormalities.⁹⁶ In one series, high-resolution sonography was found to be useful in assessing the severity of hepatic scarring and differentiating macronodular and micronodular cirrhosis.^{28,141-155}

Regenerative nodules that are 2 to 3 mm or larger in diameter can occasionally be appreciated sonographically as hypoechoic areas with echogenic borders resulting from fibrous and fatty connective tissue surrounding and separating the nodules. They can usually be seen only with high-frequency transducers unless they are quite large, in which case they may simulate a malignant neoplasm. For these reasons, ultrasound can be a difficult tool to use for screening in cirrhotic patients to detect HCC. Some studies have reported that ultrasound sensitivity for detection of HCC in screening of cirrhotic patients is only approximately 50%. The current lack of an ultrasound contrast agent to detect the vascularity indicative of tumor makes ultrasound a less reliable tool than CT or MRI for screening of cirrhotic patients.¹⁴⁸⁻¹⁵⁵

Ultrasound contrast with microbubbles, currently used in Europe and Asia, can characterize vascular patterns to differentiate cirrhotic nodules from small tumors and may be particularly useful in patients who cannot receive iodinated or gadolinium contrast agents.¹⁷³ Ultrasound elastography can also be used to assess mechanical tissues in both cirrhosis and focal tumors that have increased liver stiffness.^{174,175}

Vascular Changes

On Doppler ultrasound, phasicity is normally seen in the hepatic vein waveform from the transmission of pressure changes within the right atrium throughout the cardiac cycle. This phasicity may be decreased or absent in cirrhosis because of decreased compliance of the fibrotic liver.¹⁴⁸⁻¹⁵⁵ Narrowing of the hepatic veins from extrinsic compression can result in spectral broadening in cirrhosis. Early in cirrhosis, the portal vein flow remains hepatopetal. In more advanced cirrhosis with the development of portal hypertension, the portal vein size increases to 1.4 cm or greater, and flow can become reversed to hepatofugal (discussed later). High resistance in the hepatic artery is a nonspecific finding that can be seen in cirrhosis and

other forms of diffuse liver disease and is suggestive of but usually not used to diagnose cirrhosis. Alternatively, low arterial resistance can be present if there is significant arteriovenous or arterioportal shunting.¹⁷⁶

Extrahepatic Findings

Lymph nodes and gallstones are commonly seen on ultrasound in cirrhosis. When present, Gamna-Gandy bodies within the spleen are hyperechoic on ultrasound. Ascites, pleural effusions, and sequelae of portal hypertension can also be demonstrated.

COMPUTED TOMOGRAPHY: CIRRHOSIS

Liver Morphology

In the United States, CT¹⁵⁶⁻¹⁵⁹ is the primary noninvasive imaging modality in the evaluation of cirrhosis. Early parenchymal changes may not be visible on CT scans; however, fatty infiltration, which is the initial feature of alcoholic liver disease, is well displayed. The density of the liver is less than that of the spleen, and there is often initially hepatomegaly. Alcoholic hepatitis and hepatic steatosis are discussed more fully in other sections of this chapter.

In the later stages of cirrhosis (Fig. 89-29), the overall liver volume is diminished with the characteristic changes detailed before. Whereas all patients pathologically demonstrate regenerative nodules, these are infrequently demonstrated at CT. Nodularity of the liver contour caused by regenerative nodules, fibrous scarring, and nonuniform lobar atrophy or hypertrophy may be demonstrated, particularly in the presence of ascites. Regenerative nodules, although present pathologically in all cirrhotic livers, are visualized on multidetector CT (MDCT) in only approximately 25% of patients. Regenerative nodules, however, are most commonly isoattenuating with liver parenchyma before and after contrast material administration. Uncommonly, regenerative nodules can appear as hypoattenuating small nodules on contrast-enhanced liver CT, simulating tumor. This is most commonly seen in primary biliary cirrhosis. Siderotic nodules will appear of higher attenuation than the normal liver because of hemosiderin content; they are most apparent on unenhanced CT and appear hyperdense but usually become isoattenuating with contrast-enhanced liver parenchyma. Because of the insensitivity of CT to depict regenerative nodules, it is not able to depict or to differentiate the transformation process of regenerative nodules to dysplastic nodules. On occasion, large dysplastic nodules can be identified on unenhanced CT with increased attenuation, perhaps owing to increased iron composition or packed cellular material with increased glycogen content. Most often, however, these nodules go undetected by CT.¹⁵⁶⁻¹⁵⁹

Cirrhotic liver parenchyma often demonstrates less contrast enhancement than normal liver and appears inhomogeneous because of the underlying regeneration, fibrosis, and altered portal venous blood flow. The hepatic and portal vein radicles in the liver are often compressed and difficult to visualize. The porta hepatis and intrahepatic fissures are also unusually prominent because of the hepatic atrophy.¹⁵⁶⁻¹⁵⁹

Focal confluent fibrosis can appear at CT imaging as a focal mass, in some ways simulating tumor. It appears most conspicuous on noncontrast CT and usually either becomes isoattenuating with contrast-enhanced CT or remains slightly hypoattenuating. In some cases, the fibrosis will show irregular

contrast enhancement, making it difficult to differentiate from HCC.

These underlying parenchymal changes distort the liver parenchyma and can simulate other masses, such as HCC. In addition, the parenchymal changes can obscure subtle findings of HCC. Before the development of MDCT, it was difficult to detect even large foci of HCC in cirrhotic patients. The advent of MDCT gained the ability to optimally time contrast administration and scanning and to detect arterial phase enhancement and delayed washout, which is critical in the diagnosis of HCC and has substantially increased the ability to detect small tumors in cirrhotic patients. The appearance of HCC is discussed more fully in Chapter 87.

Vascular Findings

Small vascular shunts can be seen as focal hyperenhancement without delayed washout. The arteries may also appear tortuous with a “corkscrew” appearance in cirrhosis because of the surrounding fibrosis. The hepatic artery and portal vein may both enlarge. Intrahepatic arterial-portal fistulas are occasionally seen on CT scans in patients with cirrhosis. They cause early

opacification of the portal vein, which is best appreciated on dynamic scans by measuring the time-density curve in the aorta and the intrahepatic portal vein or hepatic hilum. In addition, the lobe that contains the arterial-portal fistula has higher density in the later arterial phase (transient hepatic attenuation difference) than the contralateral lobe.¹⁵⁶⁻¹⁵⁹

Extrahepatic Findings

Patients with cirrhosis and portal hypertension also show an increase in the density of the mesenteric fat compared with the retroperitoneal fat (56 vs 107 HU). The CT density of the mesenteric fat is also significantly higher in these patients (56 HU) than in normal subjects (107 HU).¹⁵⁶⁻¹⁵⁹ Pericaval fat collections are seen in up to 25% of patients with chronic liver disease. They are located along the posterior aspect of the IVC in most cases. The rightward angulation and narrowing of the intrahepatic IVC that occur in cirrhosis can cause the pericaval fat collections to appear intraluminal on axial CT scans.

Other findings commonly seen on CT are gallstones, lymphadenopathy, varices and other sequelae of portal hypertension, and cirrhosis-related colopathy. Gamna-Gandy bodies are often

poorly seen on CT; when present, they can appear as faint areas of increased attenuation on noncontrast CT from focal calcification.

MAGNETIC RESONANCE IMAGING: CIRRHOSIS

The role of MRI in the cirrhotic patient is to assess liver size, to evaluate the effects of portal hypertension, to screen for HCC, and to better characterize masses detected in the liver by other techniques.

Liver Morphology

MRI (Fig. 89-30; see also Figs. 89-26 and 89-27) can often detect cirrhosis at an earlier stage than CT and ultrasound can.¹⁷⁷⁻¹⁸⁷ Early in the evolution of cirrhosis, MRI can demonstrate subtle changes, such as fine strands of fibrosis and enlargement of the hilar and periportal spaces. Opposed-phase spoiled gradient-echo images, which are heavily T1 weighted, are sensitive to the depiction of subtle fibrotic change that is manifested as a lace-like hypointense network of abnormal signal intensity.⁴⁷ Linear enhancement is seen on the interstitial phase of enhancement, reflecting the distribution of gadolinium in the large extracellular spaces of the fibrotic septal tissue. There is also

enlargement of the hilar periportal space that lies anterior to the right portal vein. This is due to atrophy of segment IV and is visible in most patients with early cirrhosis.¹⁷⁷⁻¹⁸⁷

MRI is the most sensitive imaging modality for demonstration of regenerative nodules. They appear as isointense to hyperintense on T2-weighted imaging surrounded by a thin network of fibrotic change forming a hypointense background. Regenerative nodules are isointense to hypointense on T1 compared with the liver parenchyma. When hemosiderin deposits are present, these nodules may have low signal intensity on both T1- and T2-weighted imaging from magnetic susceptibility effects.¹⁷⁷⁻¹⁸⁷ These also enhance similarly to or slightly more than the background liver parenchyma during the portal venous phase of contrast administration, which is explained by their predominant portal venous blood supply. On MRI, these lesions are brightly hyperintense on T1-weighted images and hypointense to liver on T2-weighted images, although a wide variety of signal intensity combinations have been reported.¹⁶⁰⁻¹⁷⁰

Dysplastic nodules are premalignant and have a spectrum of increased cellular density and cellular atypia, which is usually classified as low or high grade. Most small dysplastic nodules are not visualized as distinct masses on MRI. Similar to regenerative nodules, surrounding fibrosis makes them distinct from

Figure 89-29 Cirrhosis: CT features. **A.** Contrast-enhanced CT scan demonstrates enlargement of the lateral segment (LS) of the left lobe, atrophy of the medial segment (solid red arrow) of the left lobe, and atrophy of the right lobe with a characteristic notch (broken yellow arrow) on the right posterior surface of the liver. Note that the gallbladder (solid yellow arrow) is in a more superficial and lateral position as a result of these morphologic changes. Several borderline size lymph nodes (broken red arrow) are present within the gastrohepatic ligament. **B.** Contrast-enhanced CT scan demonstrates widening of the gallbladder fossa (white arrow), enlargement of the lateral segment (LS) of the left lobe and caudate lobe (C) of the liver, ascites, varices (red arrow), and splenomegaly (S). **C.** Non-contrast-enhanced CT scan shows diffuse nodularity of the hepatic contour associated with enlargement of the lateral segment (LS) of the left hepatic lobe and caudate lobe (C). Note the interposition of the colon (arrow) between the liver and lateral abdominal wall. RL, Right lobe. **D.** Coronal reformatted MDCT image shows interposition of colon (arrows) between liver and right diaphragm (Chilaiditi's syndrome), which is much more common in cirrhosis due to atrophy of the right lobe. **E.** Non-contrast-enhanced CT scan shows diffuse regenerative nodules that are hyperdense due to the presence of iron. **F.** Diagram depicting method of determining the presence of caudate lobe hypertrophy and right lobe atrophy. White arrow shows transverse diameter of the caudate lobe; yellow arrow depicts diameter of right lobe. If the caudate lobe-to-right lobe ratio is larger than 0.9, the diagnosis of cirrhosis can be predicted with a fairly good accuracy. **G.** Changes in the topography of the right upper quadrant commonly highlight pericaval fat in patients with cirrhosis, often simulating a fatty mass (arrow) in the inferior vena cava.

Figure 89-30 Cirrhosis: MR features. **A.** T2-weighted MR image demonstrates enlargement of the lateral segment (LS) of the left lobe, atrophy of the medial segment (solid red arrow) of the left lobe, and atrophy of the right lobe with a characteristic notch (broken yellow arrow) on the right posterior surface of the liver. Note that the gallbladder (solid yellow arrow) is in a more superficial and lateral position as a result of these morphologic changes. C, caudate lobe. **B.** Marked atrophy of the right lobe (RL) of the liver is seen in association with enlargement of the lateral segment (LS) of the left lobe and caudate lobe (C). The gallbladder fossa is widened, and the gallbladder (yellow arrow) and hepatic flexure (red arrow) of the colon are in a superficial location. **C.** Coronal T2-weighted image shows marked hepatic atrophy associated with ascites and interposition of colon (arrow) between the liver and lateral abdominal wall. Splenomegaly is also present.

the remaining liver parenchyma. Signal characteristics of dysplastic nodules are variable and can overlap with both regenerative nodules and HCC. Dysplastic nodules are often hypointense on T2, and as dysplasia increases, the signal intensity can increase, appearing more similar to the increased T2 signal intensity of malignant disease (see Fig. 89-26). Dysplastic nodules classically appear hyperintense on T1, which does not vary with the degree of dysplasia. Dysplastic nodules are hypovascular and predominantly supplied by the portal system. Less commonly, they have an increase in hepatic arterial supply (approximately 12%), which can overlap with the appearance of HCC. When a small focus of HCC is present within a dysplastic nodule, it has been called a “nodule within a nodule” appearance with central high signal intensity of T2 with surrounding hypointensity of the dysplastic tissue. The MR characteristics of hepatic lesions during dynamic arterial, venous, and delayed phases in conjunction with serum α -fetoprotein level and number of lesions are predictors of hepatic malignant disease.¹⁸²

Liver-specific MR contrast agents (Gd-EOB-DTPA) can also help differentiate nodules from malignant changes. Regenerative nodules contain Kupffer cells and appear similar to the hepatic parenchyma during the hepatobiliary phase of imaging. With increasing dysplasia, the amount of normal hepatic function within nodules decreases and uptake is decreased with these contrast agents. However, well-differentiated HCC, which

retains some hepatocyte function, can retain these contrast agents, creating a false negative and pitfall of this technique.

Early fibrosis on MRI appears as a thin lacelike network with hyperintense T2 and hypointense T1 signal. As fibrosis progresses, these areas thicken, coalesce, and can demonstrate enhancement on delayed phase imaging. These findings are most prominent along the periphery and associated with capsular retraction and can form focal confluent fibrosis as previously described. Liver-specific contrast agents can also help demonstrate fibrosis, which will not enhance during the hepatobiliary phase, differentiating it from the liver background. Unfortunately, these signal characteristics are similar to most HCCs. As with CT, the diagnosis rests with identifying the characteristic location and capsular retraction of this lesion. When focal confluent fibrosis appears round on axial images, the high signal intensity lesions on T2-weighted images replicate findings of HCC.¹⁷⁷⁻¹⁸⁷

Several new techniques allow further assessment of hepatic fibrosis at MRI. MR elastography has shown promise as a non-invasive means of determining the degree of hepatic fibrosis. Patients with liver fibrosis have elevated MR elastographic liver stiffness measurements, which increase as fibrosis progresses, and higher stages of fibrosis can be differentiated with this technique.¹⁸⁷

Diffusion-weighted MRI may help detect cirrhosis, particularly assessment of multi-b value-generated apparent diffusion

coefficient values, which are decreased in cirrhosis. Analysis of phosphorus-based MR spectroscopy has also been investigated and has been reported to show alterations in the ratio of phosphorus-based liver metabolites.

Extrahepatic Findings

MRI is also useful in depicting Gamna-Gandy bodies (see Fig. 89-14D) in the spleen in patients with portal hypertension. These siderotic nodules are composed of hemosiderin and calcification adjacent to thickened bundles of collagen fibers and result from repeated hemorrhages in the splenic follicles or adjacent to trabeculae. These tiny nodules have low signal intensity at virtually all pulse sequences because of their paramagnetic effect but are best seen on gradient-echo or fast low-angle shot images.¹⁷⁷⁻¹⁸⁷ Other extrahepatic findings described on ultrasound and CT can also be appreciated with MRI.

ULTRASOUND: PORTAL HYPERTENSION

Sonography (Figs. 89-31 and 89-32) plays a key role in the management of patients with cirrhosis in the detection of portal hypertension and the noninvasive evaluation of the portosystemic collateral circulation. The sonographic features of portal hypertension depend on changes in size and blood flow in the portal system, congestive splenomegaly, and development of collateral pathways. Sonography is also useful in differentiating presinusoidal causes of portal hypertension from obstruction at the sinusoidal or postsinusoidal level.^{28,188,189}

Measuring portal vein size and observing respiratory variations in the superior mesenteric and splenic veins are simple and sensitive methods for detection of portal hypertension. The diameter of the portal vein in normal individuals ranges from 0.64 to 1.21 cm; the mean diameter is 1.2 cm in cirrhotic patients. There is a significant correlation between the diameter of the portal vein and maximal spleen length and the magnitude of varices seen endoscopically. A patent portal vein larger than 1.3 cm is 100% specific for portal hypertension but is seen in only 75% of cases. Other signs of portal hypertension are patency of the umbilical vein (58%); splenomegaly with dilation of splenic vein radicles (91.3%); and disappearance of normal splenic and mesenteric vessel caliber variation with respiration, which occurs in 78.5% and 88.4% of patients, respectively. Lack of distensibility of the portal vessels with respiration is an important sign. In normal individuals, the portal venous system distends with deep inspiration and breath holding because of diaphragmatic descent and compression of hepatic venous outflow. The diameter of the splenic or superior mesenteric veins may increase 50% to 100%. Ninety percent of patients with manometrically proved portal hypertension fail to show this distensibility because the portal venous system is already maximally distended and respiration-induced pressure changes are poorly transmitted through the scarred liver. The caliber of these veins decreases and respiratory variation returns if therapy with various vasoconstrictors is successful.^{28,188,189}

The size of the superior mesenteric and left gastric veins is also affected in portal hypertension. If the superior mesenteric

C, D, and E from Wachsberg RH, Bahramipour P, Sofocleous CT, et al: Hepatofugal flow in the portal venous system: Pathophysiology, imaging findings, and diagnostic pitfalls. *RadioGraphics* 22:123–140, 2002.)

vein is larger than the portal vein or the left gastric vein is larger than 4 mm, portal hypertension is present. The superior mesenteric vein and splenic veins should be no larger than 11 and 12 mm, respectively. A left gastric vein larger than 7 mm indicates a portohepatic gradient larger than 10 mm Hg, which makes variceal bleeding likely.^{28,188,189}

Collateral vessels can be seen sonographically in up to 88% of patients with portal hypertension. The most important varices involve the left gastric vein and associated esophageal varices. These varices can be identified as circular and tubular sonolucencies in the region of the gastroesophageal junction and lesser curvature of the stomach. These vessels are normally

Figure 89-32 Portal hypertension: sonographic features. **A.** Gray-scale image of the left upper quadrant demonstrates splenomegaly and ascites. **B.** Coronal Doppler image obtained through the lesser omentum demonstrates varices involving the coronary veins. **C.** Longitudinal color flow Doppler scan of the upper abdomen shows multiple collateral vessels. **D.** Caput medusae due to collateral vessels in the anterior abdominal wall in a patient with cirrhosis and portal hypertension. **E.** Gray-scale image shows enlargement of the main portal vein of 1.5 cm compatible with portal hypertension. **F.** Color and spectral Doppler image of the main portal vein in a different patient demonstrates hepatofugal flow; reversal of blood flow away from the liver with flow demonstrated below the baseline. **G.** Sagittal color Doppler sonogram showing recanalization of the umbilical vein (arrow). (**B** courtesy of Peter Cooperberg, MD, Vancouver, British Columbia, Canada.)

no larger than 4 mm. CT, however, more reliably depicts varices in this location.^{28,188,189} The portal circulation commonly decompresses through paraumbilical veins in the ligamentum teres. This usually echogenic structure becomes sonolucent centrally, producing a “bull’s-eye” appearance in the transverse plane. A central vascular channel exceeding 3 mm in diameter is a specific sign of portal hypertension. On longitudinal scans, these paraumbilical varices can be followed caudally toward the umbilicus as a tubular lucency. A patent umbilical vein excludes an extrahepatic cause of portal hypertension because the umbilical vein arises from the intrahepatic portion of the left portal vein. This vein enables the formation of an anastomosis between the left branch of the portal vein and the veins of the anterior abdominal wall, creating a portal-systemic bypass circuit known as the Cruveilhier-Baumgarten syndrome. The vein may sometimes become aneurysmally dilated and simulate a fluid collection, emphasizing the importance of Doppler assessment of cystic structures in patients with cirrhosis before biopsy. Doppler sonography can also be used to assess the hemodynamic significance of flow in the paraumbilical vein. When hepatofugal flow in the umbilical vein exceeds hepatopetal flow in the portal vein, patients are less likely to have esophageal varices and bleeding. Although it occurs more commonly in patients with severe functional impairment, it may play a protective role against variceal bleeding.^{28,188,189}

The inferior mesenteric vein also dilates in patients with portal hypertension. It provides a conduit for portosystemic shunting through two major pathways: communication with the left gonadal vein and with the middle and inferior hemorrhoidal veins. The inferior mesenteric vein is considered dilated when it is larger than 6 mm in diameter.

Duplex sonography and color flow Doppler sonography are extremely useful in patients with portal hypertension. Doppler sonography provides more precise identification and characterization of vessels and flow direction than conventional sonography does. It is particularly useful in patients with patent paraumbilical veins because patency of these channels can also be seen in normal patients but blood flow is hepatopetal, not hepatofugal as in cirrhosis. Doppler sonography can also suggest the likelihood of a spontaneous splenorenal shunt by demonstrating hepatofugal flow and dilated splenic and renal veins. The normal hepatic vein waveform (see Fig. 89-28) is triphasic because of central venous pressure variations that occur in the cardiac cycle. In patients with cirrhosis and portal hypertension, the waveforms become biphasic and ultimately monophasic. Monophasic waveforms are associated with severe portal hypertension with a sensitivity of 74% and specificity of 95%.¹⁷⁹

Other changes in the splanchnic circulation in cirrhosis and portal hypertension can also be observed with Doppler ultrasound. Superior mesenteric, splenic, and portal venous flows are significantly increased in patients with chronic cirrhosis. This is a result of increased portal inflow in cirrhosis because of a hyperdynamic circulatory state in the splanchnic circulation of the intestine and spleen in patients with portal hypertension. Not surprisingly, splenic and superior mesenteric artery blood flow also significantly increases in patients with cirrhosis compared with normal subjects and patients with chronic hepatitis. The resistive index of hepatic arterial flow is elevated (>0.78) in patients with hepatic fibrosis and portal hypertension. Although it is specific for a large portal pressure gradient, the resistive index is not sensitive. Portal venous velocity is diminished in cirrhotic patients with (7.1 ± 2.3 cm/s) and

without (12.0 ± 3.4 cm/s) spontaneous splenorenal shunts compared with normal subjects (16.5 ± 4.9 cm/s).^{28,188,189} Flow can also become reversed (hepatofugal) in the main portal vein. Decreased flow within the portal venous system in either direction increases the risk for portal venous thrombosis, another potential complication in cirrhosis and portal hypertension.

There is a correlation sonographically between hepatic venous pressure gradient and renovascular impedance. High renovascular impedance, as evidenced by elevated pulsatility and resistive indices, indicates renal vasoconstriction, which in turn indicates severe portal hypertension.¹⁷⁸

Duplex Doppler sonography should be the initial screening examination in patients with a transjugular intrahepatic portosystemic shunt (TIPS) who present with new or recurring variceal bleeding or increasing ascites when there is a question of shunt patency. It is also ideal for routine serial follow-up. Color Doppler sonography is a superb means of guiding TIPS procedures.^{28,188,189}

COMPUTED TOMOGRAPHY: PORTAL HYPERTENSION

CT (Fig. 89-33) is also excellent in demonstrating portal hypertension with its attendant varices, splenomegaly, and ascites. On CT scans, portosystemic collaterals appear as tortuous, tubular, or round soft tissue masses that may be mistaken for lymph nodes on noncontrast scans. Enhancement after intravenous administration of contrast agent confirms their vascular origin. By demonstrating selective vessel collateralization, CT also has the ability to diagnose and to differentiate their cause. Whereas short gastric and coronary collateral vessels are seen in both portal hypertension and splenic vein occlusion, enlargement of the gastroepiploic vein is seen only in splenic vein occlusion and paraumbilical varices only in portal hypertension.¹⁹⁰⁻²⁰³ Esophageal and gastric varices can be inferred from CT scans when marked enhancement is seen in association with mural thickening. Varices can also create intraluminal esophageal protrusions, giving a scalloped appearance. Liver MDCT is useful for grading of esophageal varices as well. It appears that a diameter of 3 mm for the varix is useful in identifying high-risk patients who benefit most from endoscopy and prophylactic therapy.¹⁹⁴

Although duplex Doppler sonography can provide information concerning variceal flow and direction, CT is superior in demonstrating retroperitoneal varices and in depicting azygos, hemiazygos, pericardial, and periesophageal varices that can simulate mediastinal masses.¹⁹⁰⁻²⁰³

Hepatofugal portal venous flow in patients with cirrhosis indicates the presence of advanced portal hypertension placing the patient at increased risk for hepatic dysfunction, hepatic encephalopathy, variceal bleeding, and poorer response of the varices to endoscopic ligation compared with cirrhotic patients with hepatopetal flow.²⁰¹ A portal vein diameter of less than 1 cm in the presence of cirrhosis is a highly specific but less sensitive sign of hepatofugal portal venous flow in cirrhotic patients. This implies that the liver is being almost exclusively supplied by the hepatic artery. This has important prognostic and therapeutic implications in planning chemoembolization of tumors or placement of a TIPS.

The splenic index is a good indicator of the severity of esophageal varices and hepatic functional reserve in cirrhotic patients. A splenic index (= length \times width \times thickness of

Figure 89-33 Portal hypertension: CT features. **A.** Axial CT scan showing esophageal (white arrow) and paraesophageal (red arrow) varices. Superficial collateral vessels are also present (yellow arrows). **B.** Diagram shows connections between esophageal and paraesophageal varices through perforating veins with afferent or efferent blood flow. Paraesophageal varices are formed by union of groups of dilated perforating veins, and varices connect with left gastric veins inferiorly and with azygos vein superiorly. Throughout their length, esophageal varices form connections with paraesophageal varices through perforating veins. **C.** Coronal reformatted MDCT image shows short gastric and perigastric varices (arrow). **D.** Cavernous transformation of the portal vein (arrows) is identified in this patient with portal vein thrombosis, hepatic steatosis, and splenomegaly. Note also the gastric wall varices. In the following patient, CT demonstrates colonic disease associated with cirrhosis and portal hypertension. **E.** Axial CT with contrast enhancement shows mural thickening of the right colon (yellow arrows); the left colon (not shown) was uninvolved. Note the perisplenic and gastrocolic ligament varices (red arrows). Splenomegaly is also noted. (**B** from Matsuo M, Kanematsu M, Kim T, et al: Esophageal varices: Diagnosis with gadolinium enhanced MR imaging of the liver for patients with chronic liver damage. *AJR Am J Roentgenol* 180:461–466, 2003. spleen) greater than 963 cm³ is a good indicator of the presence of esophageal varices at risk for bleeding.²⁰²

Thickening of the wall of the small bowel and colon is common in patients with cirrhosis due to the presence of portal hypertension and low protein states. There is, however, a specific right-sided colitis (see Fig. 89-33) that can be due specifically to the portal hypertension. The increased pressure within the superior mesenteric vein leads to the release of a number of inflammatory mediators, including interleukin-1 and nitrous oxide. This can lead to a colitis that simulates inflammatory bowel disease. Vascular ectasias that have a propensity to bleed may also develop. The presence of this right-sided colitis is associated with an increased risk of spontaneous bacterial peritonitis as bacteria more readily translocate through the diseased colonic wall. The imaging differential diagnosis of the colonic submucosal edema includes inflammatory bowel disease, ischemia, and infections including pseudomembranous colitis.

MAGNETIC RESONANCE IMAGING: PORTAL HYPERTENSION

MRI (Fig. 89-34) is uniquely suited for the depiction of large vascular collaterals because of the natural contrast between flowing blood and surrounding soft tissues. The most successful

MRI techniques for delineation of abdominal blood vessels are MR angiographic techniques that can be used with or without gadolinium injection. Collateral pathways are demonstrated as tortuous structures of high signal intensity on MR angiograms. Direct sagittal scans are particularly useful for imaging of the paraumbilical vein, and coronal scans are helpful for esophageal and mesenteric varices.^{47,204,205}

Increased blood supply from the hepatic artery can cause heterogeneous increased arterial enhancement of the parenchyma. Vascular shunts and occlusions can be seen similarly with MRI as with CT and MRI.

Other findings of portal hypertension, including ascites, splenomegaly, and colitis, can also be seen with MRI.

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT

The TIPS has become the mainstay of nonsurgical treatment of portal hypertension due to cirrhosis. This procedure is discussed in detail in Chapter 84. The goal of this procedure is to reduce the portal vein–hepatic vein gradient to 12 mm Hg or less. Doppler ultrasound is most commonly used to assess the TIPS and can determine patency and directionality of flow. CT and MRI can also be used to assess patency of the TIPS²⁰⁵⁻²¹¹ (Fig. 89-35).

Vascular Disorders of the Liver and Splanchnic Circulation

RICHARD M. GORE | AHMED BA-SSALAMAH

CHAPTER OUTLINE

Transient Hepatic Attenuation Differences (THADs) and Transient Hepatic Intensity Differences (THIDs)

THADs and THIDs Associated with a Mass Lesion
THADs and THIDs Not Associated with a Mass Lesion

Budd-Chiari Syndrome and Sinusoidal Obstruction Syndrome

Clinical Findings
Etiology
Pathologic Findings
Radiologic Findings
Treatment

Liver in Cardiac Disease

Clinical Findings
Radiologic Findings

Peliosis Hepatis

Pathophysiology
Radiologic Findings

Portal Vein Thrombosis

Clinical Findings
Pathophysiology
Radiologic Findings
Treatment

Cavernous Transformation of the Portal Vein

Superior Mesenteric Vein Thrombosis

Clinical Findings
Pathophysiology
Radiologic Findings
Treatment

Splenic Vein and Inferior Mesenteric Vein Thrombosis

Hepatic Infarction

Clinical Findings
Pathologic Findings
Radiologic Findings

Hemolysis, Elevated Liver Enzymes, Low Platelets (HELLP) Syndrome

Visceral Artery Aneurysms

Clinical Findings

Treatment

The liver has a unique, dual blood supply in which 25% of the flow comes from the hepatic artery and 75% through the portal vein (Fig. 90-1). There is an inverse relationship between these two blood supplies. If portal flow decreases, arterial flow will increase as if an impedance has been removed. In addition, there are several communications between these vessels that open in response to nervous and humoral factors: trans-sinusoidal, transvasal, and transplexal. When vascular compromise develops, the volume and direction of blood flow of an individual vessel will be altered. Multidetector computed tomography (MDCT), Doppler ultrasound, and magnetic resonance imaging (MRI) are sensitive in the diagnosis of these perfusion disorders and are discussed in this chapter.

Transient Hepatic Attenuation Differences (THADs) and Transient Hepatic Intensity Differences (THIDs)

Intraparenchymal perfusion disorders such as transient hepatic attenuation differences (THADs) and transient hepatic

intensity differences (THIDs) are epiphenomena of alterations of the dual vascular supply of the liver.¹⁻⁹ There is a compensatory relationship between hepatic arterial and portal venous blood supply so that arterial flow increases when portal flow decreases (Fig. 90-2). This is made possible by communication among the main vessels, sinusoids, and peribiliary venules that dilate in response to autonomic nervous system and humoral factors activated by hepatic demand for oxygen and metabolites. THADs and THIDs are areas of parenchymal enhancement visible during the hepatic arterial phase after the intravenous administration of contrast media. These lesions can be classified by morphology, etiology (Figs. 90-3 to 90-6), and pathogenesis.¹⁻⁴

THADS AND THIDS ASSOCIATED WITH A MASS LESION

Benign and malignant masses produce two morphologic types of THADs and THIDs by four pathophysiologic mechanisms: directly, by siphoning effect of the mass (lobar multisegmental shape); indirectly, by means of portal hypoperfusion (sectorial

Figure 90-1 Hepatic blood supply. **A.** Diagram shows that the arterial and venous supplies to the liver are not independent systems. There are numerous communications between them, including the trans-sinusoidal route (between the interlobular arterioles and portal venules or sinusoids) and the transplexal route (peribiliary plexus), which play an important role when portal venous inflow is compromised. GDA, Gastroduodenal artery; IMV, inferior mesenteric vein; IVC, inferior vena cava; SMV, superior mesenteric vein. **B.** Normal hepatic venous anatomy. Drawing shows major hepatic veins and short hepatic vein orifices. **C.** Normal branching pattern of the portal vein. Coronal (left) and axial (right) diagrams show that the main portal vein (1) divides into the right (2) and left portal veins. The left portal vein first courses horizontally (horizontal portion [3]), then turns anteriorly (umbilical portion [4]) toward the ligamentum teres [6]). The Cantlie line corresponds to the median fissure and extends from the gallbladder (7) to the inferior vena cava. It is located to the right of the umbilical ligament and divides the liver into right and left lobes. 5, Branch to segment IV. **D.** Four most common branching patterns of the intrahepatic portal vein. **a.** Coronal diagram shows the normal branching pattern. **b.** Coronal diagram shows trifurcation of the main portal vein. The right portal vein is not present, and the main portal vein divides into the right anterior, right posterior, and left portal veins at the same level. **c.** Coronal diagram shows the right anterior branch arising from the left portal vein. The main portal vein divides into the right posterior and left portal veins, and the right anterior portal vein arises from the left portal vein. **d.** Coronal diagram shows the right posterior branch arising from the main portal vein. The first branch to split off is the right posterior branch. The main portal vein then continues to the right for a variable distance and bifurcates into the right anterior and left portal veins. **E.** Diagram shows anatomic relationship between hepatic arterial and portal venous branches and bile duct (portal triad), biliary radicles, cords of hepatocytes, intervening sinusoid, and central draining hepatic vein. Hepatic blood supply is depicted at the sinusoidal level. Note that the bile ducts primarily derive their blood supply from the hepatic arteries.

Figure 90-1, cont'd F. Diagram of microanatomic relationship of red blood cells within sinusoid, fenestrated endothelial cells, plasma (P), space of Disse, and hepatocyte. The communication through the sinusoids of the hepatic veins and portal veins is shown. **G.** Photomicrograph showing the fenestrated walls of the sinusoids (arrow). (**A** from Quiroga S, Sebastia C, Pallisa E, et al: Improved diagnosis of hepatic perfusion disorders: Value of hepatic arterial phase imaging during helical CT. *RadioGraphics* 21:65–81, 2001. **B** from Desser TS, Sze DY, Jeffrey RB: Imaging and intervention in the hepatic veins. *AJR Am J Roentgenol* 180:1583–1591, 2003. **C** and **D** from Gallego C, Velasco M, Marcuello P, et al: Congenital and acquired anomalies of the portal venous system. *RadioGraphics* 22:141–159, 2002. **E** and **F** from Pandharipande PV, Krinsky GA, Rusinek H, Lee VS: Perfusion imaging of the liver: Current challenges and future goals. *Radiology* 234:661–673, 2005.)

Figure 90-2 The inverse relationship of portal venous and hepatic blood flow: the origin of THADs (transient hepatic attenuation differences) and THIDs (transient hepatic intensity differences). **A.** In the normal situation, a segment of liver derives most of its blood supply from the portal vein (blue) and a minority from the hepatic artery (red). **B.** If the portal vein flow is compromised (black) by obstruction or extrinsic compression or if intraparenchymal pressure exceeds portal venous pressure, that segment of liver will derive its blood supply almost exclusively from the hepatic artery (red). The normal liver will be perfused by both the hepatic artery (red) and the portal vein (blue). This has important implications for contrast-enhanced MDCT and MRI studies. (Courtesy Dennis M. Balfe, MD, St. Louis, Mo.)

shape) due to portal branch compression or infiltration; by thrombus, resulting in a portal branch blockade; or by flow diversion caused by an arteriportal shunt.¹⁻⁴

Lobar multisegmental THADs and THIDs occur when a benign hypervascular lesion or an abscess induces an increase

in the primary arterial inflow, which leads to surrounding parenchyma perfusion, the so-called siphoning effect. These THADs and THIDs do not assume a triangular shape, but a straight border may be present between the arterial phenomena from adjacent parenchyma.¹⁻⁴

Sectorial THADs and THIDs follow hepatic vessel dichotomy and appear as triangular areas that result from the strict relationship between the portal hypoperfused area and the arterial reaction. These can be seen in benign and malignant tumors as well as in abscesses due to the spread of inflammatory mediators. The THADs and THIDs can be wedge or fan shaped.¹⁻⁴

THADs AND THIDs NOT ASSOCIATED WITH A MASS LESION

THIDs and THADs can be seen in the absence of a focal lesion as a result of three mechanisms: portal hypoperfusion due to portal branch compression or thrombosis; flow diversion by arteriportal or an anomalous blood supply; or inflammation of the bile ducts or gallbladder.¹⁻⁴

Sectorial THIDs and THADs are usually caused by portal hypoperfusion due to portal vein or hepatic vein thrombosis, long-standing biliary obstruction, or arteriportal shunt that may be congenital, traumatic, or due to cirrhosis. These THIDs and THADs can have a globular shape, especially when they are adjacent to Glisson's capsule.¹⁻⁴

Polymorphous THADs and THIDs have four major causes: external compression by a rib or subcapsular collection;

Figure 90-3 THADs (transient hepatic attenuation differences) and THIDs (transient hepatic intensity differences): benign causes. Contrast-enhanced MRI (A) and MDCT (B) in a patient with a dropped gallstone and pericapsular abscess. The abscess (yellow arrow) causes increased intraparenchymal pressure exceeding portal venous pressure, leading to hyperenhancement (red arrows) from compensatory hepatic arterial flow. In a patient with sclerosing cholangitis, MR shows a THID (C, arrows) in the posterior segment of the right lobe of the liver due to a stenotic intrahepatic bile duct (D, arrow). The biliary obstruction leads to increased intraparenchymal hepatic pressure exceeding portal venous pressure, leading to the hyperenhancement.

Figure 90-4 THADs (transient hepatic attenuation differences) and THIDs (transient hepatic intensity differences) resulting from a hemangioma. Axial CT (A) and MR (B) images show a large hemangioma (H) in the lateral segment of the left lobe of the liver causing a large THAD and THID (arrows) in the medial segment of the left lobe. C. On the delayed MR image, the hemangioma (H) has filled in with contrast material, and the THID has resolved.

Figure 90-5 THADs (transient hepatic attenuation differences) and THIDs (transient hepatic intensity differences): malignant causes. **A to C.** MDCT shows a THAD (red arrows) in the lateral segment of the left hepatic lobe due to portal vein thrombosis (blue arrow) secondary to hepatocellular carcinoma (not shown). The THAD resolves on the delayed, equilibrium image (**C**). **CT (D)** and **MR (E)** images in a different patient with hepatocellular carcinoma causing portal vein thrombosis (yellow arrow). Notice the THID (**D**) and THID (**E**) in the right lobe of the liver.

anomalous blood supply from atypical arteries, collateral venous vessels, or accessory veins, especially in segment IV of the liver; inflammation of adjacent organs, such as cholecystitis and pancreatitis that spread inflammatory mediators and reduce portal inflow because of interstitial edema; and trauma, biopsy, or radiofrequency ablation of hepatic tumors.¹⁻⁴

In patients with obstruction of the superior vena cava, the medial segment of the left lobe (segment IV) of the liver will hyperenhance because of collateral veins. The internal mammary vein connects to the left portal vein by the paraumbilical vein.

Diffuse THADs and THIDs can be seen in right-sided heart failure (see later), Budd-Chiari syndrome (see later), and biliary obstruction, leading to abnormal attenuation and signal intensity adjacent to the portal triads.

Budd-Chiari Syndrome and Sinusoidal Obstruction Syndrome

The term *Budd-Chiari syndrome* is applied to a diverse group of conditions associated with hepatic venous outflow obstruction, at the level of either the large hepatic veins or the suprahepatic segment of the inferior vena cava. Diagnosis of this disorder is frequently difficult because of its protean causes and clinical manifestations. Sinusoidal obstruction syndrome is a subset of the Budd-Chiari syndrome in which nonthrombotic occlusion of the small pre-sinusoidal venules occurs. This usually develops in the setting of chemotherapy, radiation therapy, and immunosuppressive therapy.¹⁰⁻²¹

Figure 90-6 THADs (transient hepatic attenuation differences) due to superior vena cava obstruction by lung cancer. A. Axial CT scan shows robust enhancement of the medial segment of the left lobe of the liver (arrow). **B.** Diagram depicting the decompression pathways responsible for this THAD. HCV, Hepatic central veins; IMV, internal mammary vein; IPV, inferior phrenic vein; SVC, superior vena cava. (B from Cihangiroglu M, Lin BH, Dachman AH: Collateral pathways in superior vena caval obstruction as seen on CT. *J Comput Assist Tomogr* 25:1–8, 2001.)

CLINICAL FINDINGS

The two major clinical presentations of Budd-Chiari syndrome are determined by the extent and speed of onset of venous occlusion. The acute form follows simultaneous obstruction of all three hepatic veins or, more frequently, obstruction of the last patent hepatic vein after previous, clinically occult thrombosis of the others. These patients experience rapid onset of abdominal pain, tender hepatomegaly, vomiting, ascites, and arterial hypotension. This constellation of findings is associated with mild or marked increase of serum bilirubin level, marked elevation of the transaminase values, and decreased clotting factors resulting from hepatocellular failure.¹⁰⁻²¹

BOX 90-1 CAUSES OF BUDD-CHIARI SYNDROME

HYPERCOAGULABLE STATES

- Antiphospholipid syndrome
- Antithrombin III deficiency
- Essential thrombocytosis
- Factor V Leiden
- Lupus anticoagulant
- Myeloproliferative disorder
- Paroxysmal nocturnal hemoglobinuria
- Polycythemia rubra vera
- Postpartum thrombocytopenic purpura
- Protein C deficiency
- Protein S deficiency
- Sickle cell disease

INFECTION

- Amebic liver abscess
- Aspergillosis
- Filariasis
- Hepatic abscess
- Hydatid cysts
- Pelvic cellulitis
- Schistosomiasis
- Syphilis
- Tuberculosis

CANCER

- Adrenal cancer
- Bronchogenic carcinoma
- Fibrolamellar cancer
- Hepatoma
- Leiomyosarcoma
- Leukemia
- Renal cell cancer
- Rhabdomyosarcoma

MISCELLANEOUS

- Behçet's disease
- Celiac disease
- Crohn's disease
- Laparoscopic cholecystectomy
- Membranous obstruction of vena cava
- Oral contraceptives
- Polycystic disease
- Pregnancy
- Sarcoidosis
- Trauma

Patients with the chronic form of Budd-Chiari syndrome present with ascites of insidious onset, right upper quadrant pain, hepatomegaly, normal or moderately increased transaminase values, decreased albumin and clotting factors, mild jaundice, and splenomegaly or variceal bleeding if cirrhosis develops. The diagnosis is seldom made on clinical grounds alone because clinicians tend to ignore the abdominal pain and ascribe the hepatomegaly and ascites to cirrhosis. The correct diagnosis may be inferred from the absence of a cause for the cirrhosis; episodes of abdominal pain during the preceding month; or, uncommonly, a palpable caudate lobe.¹⁰⁻²¹

ETIOLOGY

Budd-Chiari syndrome is classified as either primary or secondary, depending on the cause and pathophysiologic manifestations (Box 90-1). In the primary type, there is total or incomplete membranous obstruction of hepatic venous blood, either above the entrance of the hepatic veins into the inferior vena cava or

between the ostium of the right hepatic vein, which remains patent, and the more superior middle and left hepatic veins. Membranous obstruction, although uncommon in Europe and North America, is the most common cause of Budd-Chiari syndrome in Japan, India, Israel, and South Africa. These membranes vary greatly in size, from wafer thin to several centimeters thick. The origin of this lesion is controversial; most are believed to be congenital malformations that result from deviations of the complex embryologic process by which the inferior vena cava is formed. Other theories suggest that some of these lesions are acquired secondary to mechanical injury, infection, phlebitis, or organization of a preexisting thrombus. This origin would explain the adult presentation of the disorder.⁶⁻²¹

Membranous obstruction of the inferior vena cava is complicated by hepatocellular carcinoma in 20% to 40% of cases in South African and Japanese series. It is postulated that the obstruction renders the hepatocytes more susceptible to the action of one or more environmental carcinogens or that perhaps long-standing venous obstruction induces formation of hyperplastic nodules, which may undergo malignant transformation.⁶⁻²¹

Secondary Budd-Chiari syndrome can be classified on the basis of the site of hepatic venous obstruction. Obstruction at the level of the central and sublobular veins may follow chemotherapy with thioguanine, vincristine, cytarabine, 6-mercaptopurine, or dacarbazine; internal or external hepatic radiation; chemoradiation therapy before bone marrow transplantation; azathioprine for immunosuppression; arsenic poisoning; pregnancy (particularly in the postpartum period); and oral contraceptive use. Naturally occurring toxins, such as the pyrrolizidine alkaloids found in herbal teas containing senecio and aflatoxins, have been implicated as well. Nonthrombotic occlusion of small central and sublobular veins is termed sinusoidal obstruction syndrome.⁶⁻²¹

Sinusoidal obstruction syndrome (also known as hepatic veno-occlusive disease) is a distinctive and potentially fatal form of hepatic injury that occurs after drug and toxin exposure. Obstruction of the sinusoids occurs in central areas with hepatocyte necrosis and hemorrhage. Endothelial injury is the initiating event. Sinusoidal obstruction syndrome produces a hypercoagulable state. The venular and sinusoidal lumens are reduced because of edema and partial to complete fibrosis of venular lumens. Cyclophosphamide is the most common agent.

Obstruction of the major hepatic veins may occur in the setting of polycythemia vera, paroxysmal nocturnal hemoglobinuria, myeloproliferative disorders, thrombocytosis, hyper-eosinophilic syndrome, sickle cell anemia, Behçet's disease, anticardiolipin antibodies, lupus anticoagulant, protein S or C deficiency, antithrombin III deficiency, antiphospholipid antibodies, mixed connective tissue disease, and Sjögren's syndrome.⁶⁻²¹

A variety of hepatic and extrahepatic masses can also compress the inferior vena cava and hepatic veins. These masses are the second most common mechanism of hepatic venous outflow block in Western countries. Hepatocellular carcinoma, hypernephroma, adrenal and bronchial carcinomas, leiomyosarcoma of the inferior vena cava, and hepatic adenoma or cystadenoma are the most common neoplasms associated with Budd-Chiari syndrome. Benign masses, such as hydatid cysts, intrahepatic hematoma, Caroli's disease, large simple cysts, and amebic abscesses, can also cause obstruction.⁶⁻²¹

PATHOLOGIC FINDINGS

In acute Budd-Chiari syndrome, the liver is markedly enlarged and reddish (Fig. 90-7A-C). On histologic examination, sinusoidal dilation is evident, and parenchymal damage ranges from mild atrophy to marked hemorrhagic necrosis in the centrilobular areas.

In chronic Budd-Chiari syndrome, the liver is nodular and irregular in shape, often with caudate lobe hypertrophy. Centrilobular fibrosis is the hallmark of this disorder, and the centrally scarred areas may link to form connective tissue bridges. Sinusoidal dilation also predominates around hepatic venules and is associated with liver cell atrophy and perisinusoidal fibrosis.

In sinusoidal obstruction syndrome, the venular and sinusoidal lumens are reduced because of edema and partial to complete fibrosis of venular lumens (Fig. 90-7D).

Regenerative nodules are often seen in Budd-Chiari syndrome and are usually multiple, measuring between 5 and 40 mm. They develop in the setting of insufficient blood supply to the liver, leading to atrophy along with compensatory nodular hyperplasia in areas of hepatic parenchyma that have an adequate blood supply. The nodules are composed of hyperplastic hepatocytes arranged in plates of one or two cells in width. The nodules grow in an expansile fashion, compressing the surrounding liver and obliterating the central vein. There is no evidence that these nodules degenerate into malignancy.⁶⁻²¹

RADIOLOGIC FINDINGS

Traditionally, the radiographic "gold standard" for the diagnosis of Budd-Chiari syndrome has been hepatic venography and cavography. However, these invasive angiographic procedures are not suitable for screening of patients with nonspecific signs and symptoms. The cross-sectional imaging modalities have proved successful in the diagnosis of this disorder, and such studies can usually obviate angiography or venography.

Ultrasound

Because of its excellent sensitivity, high specificity, noninvasiveness, relatively low cost, availability, lack of contrast requirements, and multiplanar imaging ability, sonography can be the initial screening study for the Budd-Chiari syndrome. The sonographic features (Fig. 90-8) of the Budd-Chiari syndrome are stenosis of hepatic veins (which often have thick, echogenic walls and proximal dilation), echogenic intravenous thrombi, intrahepatic collaterals or extrahepatic anastomoses, and large inferior right hepatic vein.²²⁻²⁴

In chronic cases, the hepatic veins may not be visible. The inferior vena cava may also be narrowed by a grossly swollen liver. Ascites, abnormal hepatic shape with enlargement of the caudate lobe, and atrophy of the right lobe are present in most cases except in disease of acute onset. When both the left lobe and the caudate lobe are enlarged, confusion with cirrhosis can occur. Membranous webs are identified as echogenic or focal oblations of the lumen.²²⁻²⁴

In patients with hepatomegaly, evaluation of the hepatic veins can be difficult because they are often compressed and may not be visible. In these patients, an abdomen distended by ascites can further interfere with sonography. Similarly, in cirrhotic livers, patent hepatic veins may be difficult to identify, which precludes placement of the duplex Doppler cursor.

Figure 90-7 Budd-Chiari syndrome and sinusoidal obstruction syndrome: pathologic findings. **A.** Photomicrograph showing thrombus (arrow) within a subsegmental hepatic vein in this patient with polycythemia vera. **B.** Tumor thrombus from a renal cell carcinoma has propagated superiorly to involve the inferior vena cava (arrow) and hepatic veins. **C.** Gross autopsy specimen reveals relative central sparing of the caudate (C) lobe (arrow) associated with marked hemorrhagic congestion of the periphery of the liver. **D.** In a patient with sinusoidal obstruction syndrome, there is occlusive fibrosis of a small intrahepatic vein (V) seen on pathologic examination.

Visualization of hepatic webs is also a problem. Color flow Doppler examination may be helpful in these cases.²²⁻²⁴

Absent or reversed flow in the hepatic veins or flat flow in the hepatic veins associated with reversed flow in the inferior vena cava as demonstrated by duplex Doppler ultrasound is diagnostic of Budd-Chiari syndrome. The flow in the portal vein may be slow or reversed.

Color Doppler sonography overcomes some of the limitations of real-time sonography by demonstrating reversed flow in the retrohepatic inferior vena cava, documenting the presence of intrahepatic venous collaterals, and confirming the absence of flow in presumably thrombosed vessels. Color flow imaging rapidly and accurately determines the status of the hepatic veins and inferior vena cava and the direction of flow. Areas of occlusion are also clearly depicted, as are areas of narrowing, tortuosity, and reversal of flow direction.²²⁻²⁴

In sinusoidal obstruction syndrome, there is nonthrombotic occlusion of small hepatic veins and terminal hepatic venules, the major hepatic veins show normal hepatofugal flow

direction, and the inferior vena cava is patent with flow toward the heart. Decreased, reversed, or to-and-fro flow (flow demodulation) may be seen in the main portal vein. Other Doppler criteria include decrease in spectral density, reversed flow or maximum flow in the main portal vein of 210 cm/s, portal vein congestion index (cross-sectional area of vein divided by average velocity), hepatic artery resistive index of 0.75 or greater, monophasic flow in the hepatic veins, and flow recorded in paraumbilical veins. Gray-scale criteria include hepatic vein diameter of less than 3 mm, portal vein diameter of more than 8 mm in children and more than 12 mm in adults, and mural thickening of the gallbladder of more than 6 mm. Nonspecific findings include hepatosplenomegaly, ascites, and visualization of paraumbilical veins.²²⁻²⁴

Computed Tomography

The CT features of Budd-Chiari syndrome depend on the age and extent of the obstruction and the presence of coexisting changes in portal venous blood flow.^{25,26} On noncontrast scans,

Figure 90-8 Budd-Chiari syndrome: sonographic findings. **A.** Axial scan shows thrombus in the inferior vena cava (arrow). Note the large right-sided pleural effusion. **B.** Coronal oblique scan shows thrombus within the middle hepatic vein (arrow). **C.** Sagittal sonogram in a different patient shows a thin fibrous web (arrow) across the inferior vena cava (IVC).

in the acute phase of the disease, diffuse hepatic hypodensity is associated with global liver enlargement and ascites. The hepatic hypodensity is presumably due to hepatic parenchymal congestion. Hyperdense thrombus with an attenuation of 38 to 42 HU may be seen in the inferior vena cava and hepatic veins. Rarely, a calcified caval membrane is identified. After the injection of contrast material, the liver typically shows patchy enhancement; this is due to the hepatic congestion, which causes portal and sinusoidal stasis. In most patients, the central regions of the liver, including the caudate lobe and part of the left lobe, may enhance normally and appear hyperdense compared with the more peripheral parts of the liver, which show decreased enhancement. Later, a classic “flip-flop” pattern may develop (Fig. 90-9), in which the contrast material from the normally enhanced central liver washes out so that this region becomes relatively hypodense compared with the peripheral zones, which are slowly accreting contrast material. The subcapsular portions of the liver may enhance normally because they have independent venous drainage through systemic subcapsular veins. These differences in hepatic attenuation and morphologic changes are closely related to regional disturbances in portal flow. In segments of the liver in which venous drainage is obstructed (the hepatic periphery), portal blood flow is diminished, if not reversed. Portal venous flow is normal in the central portion of the liver, where hepatic venous egress is uninterrupted.^{25,26}

Intravascular thrombus is best seen in the acute phase of the Budd-Chiari syndrome as a low-density mass in the lumen of

the hepatic veins and inferior vena cava. The wall of the thrombosed vessel may appear dense relative to the thrombus secondary to the enhancement of the vasa vasorum. The involved vessel also is often enlarged. Portal vein thrombus may be seen in 20% of cases. Compression of the inferior vena cava is also demonstrated²⁴⁻²⁶ (Fig. 90-10).

In more chronic cases of Budd-Chiari syndrome, the thrombi and the hepatic veins are often difficult to visualize. Intravascular thrombus density, which is high for the first 3 weeks, also diminishes over time. As the obstruction becomes more chronic, the liver undergoes morphologic changes that are due to diminished or reversed portal blood flow in the involved hepatic segments. Portal venous blood carries certain hepatotropic agents, mainly insulin, and segments deprived of these agents experience nutritional ischemia and eventually atrophy. Accordingly, the caudate lobe exhibits hypertrophy, and the periphery of the liver tends to exhibit atrophy. These changes may take 2 to 4 months to appear. Unless the membranes are calcified, membranous obstruction of the inferior vena cava is more difficult to visualize.

On MDCT, large regenerative nodules robustly and homogeneously enhance during the arterial dominant phase and remain slightly hyperdense on the portal venous dominant phase images as well.

Magnetic Resonance Imaging

MRI is a useful screening modality for Budd-Chiari syndrome by virtue of its ability to display directly the portal veins, hepatic

Figure 90-9 Budd-Chiari syndrome: flip-flop pattern on MR. The classic CT flip-flop pattern of hepatic contrast enhancement is shown in this patient with Budd-Chiari syndrome. **A.** Contrast-enhanced MR image of the liver shows rapid enhancement (arrow) of the unobstructed central portion of the liver with a delayed peripheral hepatogram. **B.** Delayed image shows that the central, unobstructed portion of the liver (arrow) has washed out, while the periphery is slowly accreting contrast material.

Figure 90-10 Budd-Chiari syndrome: CT features with MR and ultrasound correlation. CT (**A**), MR (**B** and **C**), and sonographic (**D**) images of the liver show a mottled contrast enhancement pattern and narrowing of the inferior vena cava and no discernible hepatic veins.

veins, and inferior vena cava in numerous planes. A number of specific MRI abnormalities²⁷⁻²⁹ are associated with this syndrome (Figs. 90-11 to 90-15): complete absence of hepatic veins or striking attenuation of their caliber, demonstration of thrombus or absent vascular flow in hepatic veins, comma-shaped intrahepatic collateral vessels, and marked constriction of the inferior vena cava. Less specific findings include enlargement of the caudate lobe, ascites, and inhomogeneity of the hepatic parenchyma. Vascular patency can confidently be confirmed when the vessel has no signal.

The multiplanar capabilities of MRI are of great value in depicting tumor thrombus in patients with Budd-Chiari

syndrome secondary to neoplasm. Bland and tumor thrombus can be distinguished by the administration of gadolinium. Tumor thrombus may show contrast enhancement.²⁷⁻²⁹

The degree of enhancement of the liver parenchyma supplied by a thrombosed hepatic vein depends on the acuteness and duration of the thrombosis. Involved parenchyma enhances less than surrounding liver in acute thrombosis. In chronic thrombosis, enhancement is more variable and may be increased. In patients with acute Budd-Chiari syndrome, the congested liver may have a higher water content and longer T2 relaxation time than the spared caudate lobe. Also, the peripheral liver enhances less than the central liver after intravenous

Figure 90-11 Budd-Chiari syndrome: MRI findings in a patient with hepatocellular carcinoma invading the hepatic veins and inferior vena cava. Coronal (A) and parasagittal (B) images shows tumor thrombus (arrows) invading the inferior vena cava and right atrium.

Figure 90-12 Acute Budd-Chiari syndrome: MR findings. The liver is edematous and inhomogeneous in signal intensity on this MR image.

administration of gadolinium because of increased parenchymal pressure with resultant diminished blood supply from both the hepatic artery and the portal vein.

Large regenerative nodules are bright on T1-weighted MR images and show the same enhancement pattern after the intravenous administration of gadopentetate dimeglumine (Gd-DTPA). They are predominantly isointense or hypointense relative to the liver on T2-weighted images.²⁷⁻²⁹

Angiography

Angiography (Fig. 90-16) has traditionally been the radiographic gold standard for the evaluation of patients with Budd-Chiari syndrome. Now it is seldom performed for diagnosis but

Figure 90-13 Subacute Budd-Chiari syndrome: MRI findings. T2-weighted MR image shows caudate lobe (C) hypertrophy. The periphery of the liver is hyperintense, indicating edema. There is a small amount of ascites.

as a preliminary procedure to radiologic interventions, such as transjugular intrahepatic portosystemic shunt (TIPS) creation, balloon angioplasty, or stricture stenting.

Nodular Regenerative Hyperplasia

On contrast-enhanced CT and MRI studies, multiple enhancing nodules are identified that are usually 5 to 7 mm in diameter³⁰⁻³³ (Fig. 90-17).

TREATMENT

The treatment and prognosis of Budd-Chiari syndrome are determined by the rate and degree of hepatic outflow obstruction. In acute Budd-Chiari syndrome, survival time may be short because of acute liver failure or extension of thrombus into the inferior vena cava with resulting pulmonary emboli. Patients with chronic Budd-Chiari syndrome generally succumb to variceal bleeding secondary to severe cirrhosis and portal

Figure 90-14 Chronic Budd-Chiari syndrome: MRI findings. **A.** Postgadolinium image shows no demonstrable inferior vena cava or hepatic veins. Note the dilated azygos vein (red arrow), hemiazygos vein (white arrow), and superficial collateral (yellow arrow) blood vessels. **B.** T2-weighted image shows inhomogeneous, coarsened hepatic parenchyma. Ascites is present.

Figure 90-15 Sinusoidal obstruction syndrome: CT findings. Axial CT images in two different patients (**A** and **B**) show a mottled contrast enhancement pattern and narrowing of the right hepatic vein (arrows). This latter finding is suggestive of sinusoidal obstruction syndrome in the appropriate clinical setting.

Figure 90-16 Budd-Chiari syndrome: angiographic features. Digital subtraction angiogram shows a web (arrow) obstructing the inferior vena cava.

hypertension. Most patients require portal decompression to prevent liver failure and to resolve the ascites.³⁴⁻⁴²

Treatment of Budd-Chiari syndrome depends on the cause. In some cases, medical management with large doses of steroids (for idiopathic granulomatous venulitis) or nutritional therapy (for an acutely enlarged, fatty liver compressing the inferior vena cava) may suffice. However, in most cases, medical therapy is limited and is directed toward anticoagulation and the control of ascites with diuretics.

Membranous obstructions of the inferior vena cava (see Fig. 90-16) and the hepatic veins are amenable to angioplasty with balloons or lasers and stent insertion. Before any intervention, these patients should receive anticoagulants because of the danger of pulmonary emboli from venous thrombi proximal to the membranes. This danger is the major risk of thrombolytic therapy as well. Angioplasty is more difficult in patients with extensive thrombus, but clinical improvement may accompany dilation and recanalization of only one hepatic vein.³⁴⁻⁴²

Reports suggest the utility of expandable metal stents in the treatment of Budd-Chiari syndrome resulting from tumor compression or from idiopathic obstruction of the inferior vena

cava. The TIPS procedure is useful in treating Budd-Chiari syndrome as well.³⁴⁻⁴²

The surgical alternatives in Budd-Chiari syndrome are as follows: direct repair by membranotomy, membranectomy, or cavoplasty; portosystemic decompression by side-to-side portacaval or mesoatrial shunt; transplantation; and peritoneo-jugular shunt.

Liver in Cardiac Disease

Passive hepatic congestion is caused by stasis of blood within the liver parenchyma as a result of compromise of hepatic venous drainage. It is a common complication of congestive heart failure and constrictive pericarditis, wherein elevated central venous pressure is directly transmitted from the right atrium to the hepatic veins because of their close anatomic relationship. The liver becomes tensely swollen as the hepatic sinusoids engorge and dilate with blood (Fig. 90-18). These changes may be transient, and full recovery follows once the patient's congestive heart failure is corrected. In chronic right atrial failure, cardiac cirrhosis may ensue.⁴³⁻⁴⁹

Figure 90-17 Budd-Chiari syndrome: nodular regenerative hyperplasia. Multiple hypervascular lesions (arrows) are identified on contrast-enhanced CT. (Case courtesy Michael P. Federle, MD, Stanford University.)

CLINICAL FINDINGS

With acute congestion, the liver is enlarged and tender, and the patient may have severe right upper quadrant pain that is due to stretching of Glisson's capsule. Patients typically have hepa-tojugular reflux on physical examination. Liver function abnormalities are often mild, but florid hepatic dysfunction simulating acute viral hepatitis may be seen. The diagnosis is usually not made clinically because the signs and symptoms of cardiac failure overshadow those of liver disease. In rare cases of cardiomyopathy, the patient may present with hepatic failure before cardiac disease is recognized as the cause of the hepatic dysfunction.

RADIOLOGIC FINDINGS

Ultrasound

Ultrasound demonstrates hepatic enlargement and dilation of the inferior vena cava and hepatic veins in the early stages of this disorder (Fig. 90-19). Normally, the maximal diameter of the main trunk of the right hepatic vein is 5.6 to 6.2 mm. In patients with congestive heart failure, the mean diameter is 8.8 mm, and it increases to 13.3 mm if there is associated pericardial effusion. Respiratory variations in the caliber of the inferior vena cava and hepatic veins are diminished.

The spectral Doppler waveform of the hepatic vein is also altered. Normally, the inferior vena cava and hepatic veins show a triphasic flow pattern: the first two peaks are toward the heart and are reflections of right atrial and ventricular diastole; the third peak is a short period of reversed blood flow, which accompanies atrial systole (the p wave of the electrocardiogram). In patients with elevated central venous pressure, the hepatic veins lose their triphasic pattern. The spectral signal may have an M shape, and ultimately, in cardiac cirrhosis, a unidirectional, low-velocity continuous flow pattern may be seen.⁴³⁻⁴⁹

In tricuspid regurgitation, the normally triphasic hepatic vein demonstrates a decrease in the size of the antegrade systolic wave and a systolic/diastolic flow velocity ratio less than 0.6 (normal >4.0). The high systolic pressure of the right atrium is transmitted to the inferior vena cava and hepatic veins.⁴³⁻⁴⁹

In patients with severe congestive heart failure, the portal venous Doppler signal may also be altered by the mechanical events in the right side of the heart. Normally, the portal vein shows almost continuous flow except for some increase during inspiration. In passive hepatic congestion, the energy of the

Figure 90-18 Passive hepatic congestion: pathologic findings. A. Classic "nutmeg liver" in a patient with chronic passive hepatic congestion. **B.** Dilated sinusoids are seen surrounding a dilated central hepatic vein (arrow).

Figure 90-19 Passive hepatic congestion: sonographic findings. **A.** Color Doppler axial sonogram shows a dilated inferior vena cava and hepatic veins with turbulent flow. **B.** In passive hepatic congestion, the normal triphasic hepatic venous pattern is lost. **C.** Increased portal vein pulsatility is commonly seen in passive hepatic congestion as cardiac pulsations are transmitted through the dilated hepatic sinusoids to the portal vein.

elevated pressure from the right atrium and hepatic vein is transmitted directly through the dilated hepatic sinusoids into the portal vein. This energy transmission causes increased pulsatility of the portal venous Doppler signal because the liver no longer prevents changes in central venous pressure from reaching the portal circulation. This pulsatility is manifested by monophasic forward flow with peak velocity at ventricular diastole and gradual diminution of velocity throughout ventricular systole, a reversal of flow during ventricular systole, or vena cava–like biphasic forward velocity peaks during each cardiac cycle.⁴³⁻⁴⁹

As cardiac cirrhosis develops, the morphology of the liver becomes similar to that observed with cirrhosis resulting from other causes. Patients with other forms of cirrhosis may also show flattening of the Doppler waveform in the hepatic veins because of impaired mural compliance of these vessels.

Computed Tomography

The CT findings (Fig. 90-20) of passive hepatic congestion include dilation of the cava and the hepatic veins. When a bolus of contrast material injected intravenously through an arm vein reaches the failing right atrium, it may flow directly into the inferior vena cava and hepatic veins rather than flow normally into the right ventricle. The elevated central venous pressure permits retrograde opacification and enhancement of the inferior vena cava and hepatic veins. Contrast-enhanced CT scans may show an inhomogeneous, mottled, reticulated-mosaic pattern of parenchymal contrast enhancement. The abnormal hepatogram is presumably due to impaired venous outflow leading to altered hepatic hemodynamics and hepatic parenchymal distortion. Linear and curvilinear regions of poor

enhancement may be due to delayed enhancement in regions of small and medium-sized hepatic veins. Larger patchy regions of poor or delayed enhancement in the periphery of the liver probably are a manifestation of the stagnant blood flow in these regions in patients with hepatic venous hypertension. This stagnant blood most likely affects inflow from hepatic arterial and portal venous circulations. Ancillary findings include cardiomegaly, hepatomegaly, intrahepatic periportal lucency resulting from perivascular lymphedema, pleural effusions, ascites, and pericardial effusions.⁴³⁻⁴⁹

Magnetic Resonance Imaging

On early MRI contrast-enhanced images, the liver may enhance in a mosaic fashion with a reticulated pattern of low signal intensity linear markings. The signal intensity of the liver becomes more homogeneous by 1 minute. There is often dilation of the hepatic veins and suprahepatic inferior vena cava. As on CT, contrast material injected into an arm vein may reflux into the hepatic veins and suprahepatic inferior vena cava, enhancing these structures before the portal vein. On gradient-echo MR images, slow or even absent antegrade flow within the inferior vena cava may be identified.⁴³⁻⁴⁹

Peliosis Hepatis

Peliosis hepatis is a rare disorder characterized by cystic hepatic sinusoidal dilation and the presence of multiple blood-filled lacunar spaces of various sizes (1 mm to 3 cm) throughout the liver. These peliotic lesions can also occur in the spleen, bone marrow, lymph nodes, and lungs. The blood-filled spaces freely communicate with the sinusoids and are lined by a thin band

Figure 90-20 Passive hepatic congestion: CT features. Coronal (A) and sagittal (B) reformatted MDCT images demonstrate reflux of contrast material into a dilated inferior vena cava (arrows) and hepatic veins. C. Axial scan in a different patient with a dissecting thoracoabdominal aortic aneurysm shows a dilated inferior vena cava and hepatic veins (arrows). D. Delayed image of patient shown in C reveals a mottled enhancement pattern typical of passive hepatic congestion.

of collagenous tissue and endothelial cells. Peliosis lesions can be differentiated from hemangiomas by the presence of portal tracts within the fibrous stroma of the blood spaces.⁵⁰⁻⁵⁷

PATHOPHYSIOLOGY

Numerous theories have been proposed for the cause of peliosis hepatitis, including outflow obstruction at the sinusoid wall and hepatocellular necrosis leading to cyst formation. There is dilation of a portion of the central vein of the hepatic lobule. Peliosis hepatitis develops in the following settings: with use of anabolic steroids, corticosteroids, tamoxifen, oral contraceptives, or diethylstilbestrol; after renal or cardiac transplantation; in association with a chronic wasting disease, such as tuberculosis, leprosy, malignant disease, or acquired immunodeficiency syndrome (AIDS); in association with celiac diseases, diabetes, necrotizing vasculitis, or Hodgkin's lymphoma; and after exposure to polyvinyl chloride or arsenic.⁵⁰⁻⁵⁷

Peliosis hepatitis is usually found incidentally at autopsy, but it can cause hepatic failure or liver rupture with hemoperitoneum and shock. Patients sometimes present with hepatomegaly, portal hypertension, esophageal varices, and ascites.

RADIOLOGIC FINDINGS

The diagnosis of peliosis hepatitis requires a high degree of suspicion because the radiographic and sonographic findings are nonspecific. On sonographic evaluation, the hepatic echo pattern is inhomogeneous, with hyperechoic and hypoechoic regions, predominantly in the right lobe.

Detecting lesions on CT scans is difficult unless there is associated fatty infiltration to contrast the higher density aggregation of blood-filled spaces (Fig. 90-21). After bolus administration of contrast material, these lesions may appear hypodense early and isodense with time. On angiography, the peliotic lesions are manifested as multiple small accumulations of contrast material on the late arterial phase that become more prominent on the parenchymal and venous phases.⁵⁰⁻⁵⁷

Portal Vein Thrombosis

Portal vein thrombosis is the leading cause of presinusoidal hypertension in the United States. The patency of this vessel is of major concern in the following groups of patients: newborn infants with umbilical catheters who present with ascites,

Figure 90-21 Peliosis hepatis. Multiple small lakes of contrast material are present on this CT scan. The patient also has ascites.

cirrhosis patients who experience sudden decompensation of their disease and exacerbation of ascites, and liver transplant recipients. In some patients, portal vein obstruction is often a diagnosis of exclusion, whereas in others, it is first manifested as a major variceal hemorrhage or vascular emergency. In many cases, splanchnic vein thrombosis is found incidentally in patients with mild, nondescript abdominal pain.⁵⁸⁻⁶⁰

CLINICAL FINDINGS

The clinical presentation of portal vein thrombosis depends on how acutely the obstruction develops and its underlying cause. In most cases, the disease is manifested insidiously, with nonspecific abdominal pain and other manifestations of portal hypertension, including splenomegaly, varices, and massive, intractable ascites, which is a poor prognostic sign. If the thrombosis is due to septic pyelophlebitis, the patient may present with hepatomegaly, pyrexia, leukocytosis, and liver abscesses. In some cases, the disease is manifested catastrophically, with intestinal infarction or massive variceal hemorrhage.⁵⁸⁻⁶⁰

PATHOPHYSIOLOGY

The portal vein may develop a thrombus in its intrahepatic or extrahepatic course, and in 50% of cases, no cause may be apparent (Box 90-2). The most common extrahepatic causes of portal vein occlusion in the West are cancer of the stomach or pancreas and cholangiocarcinoma; acute diverticulitis or appendicitis initiating pyelophlebitis in the portal vein or mesenteric veins; pancreatitis or carcinoma of the pancreas that initiates thrombosis of the splenic vein followed by propagation into the main portal vein; postsurgical thrombosis after upper abdominal procedures, such as splenectomy, endoscopic injection sclerotherapy, and liver transplantation; and trauma. Worldwide, schistosomiasis is the most common cause of portal vein obstruction and the leading cause of portal hypertension.⁵⁸⁻⁶⁰

BOX 90-2 CAUSES OF PORTAL VEIN THROMBOSIS

HYPERCOAGULABLE STATES

- Antiphospholipid syndrome
- Factor V mutations
- Paroxysmal nocturnal hemoglobinuria
- Myeloproliferative diseases
- Oral contraceptives
- Polycythemia rubra vera
- Pregnancy
- Protein S deficiency
- Sickle cell disease

INFLAMMATORY DISEASE

- Behçet's disease
- Crohn's disease
- Pancreatitis
- Ulcerative colitis

COMPLICATIONS OF MEDICAL INTERVENTION

- Alcohol injection
- Ambulatory dialysis
- Chemoembolization
- Islet cell injection
- Liver transplantation
- Partial hepatectomy
- Sclerotherapy
- Splenectomy
- Transjugular intrahepatic portosystemic shunt
- Umbilical catheterization

INFECTIONS

- Actinomycosis
- Appendicitis
- Candida albicans* infection
- Diverticulitis

MISCELLANEOUS

- Cirrhosis
- Bladder cancer
- Nodular regenerative hyperplasia

Cirrhosis is the most common intrahepatic cause of portal vein thrombosis. It is estimated that 10% of patients with cirrhosis of the liver have portal vein thrombosis because stagnant intrahepatic flow predisposes to thrombus formation. These patients are more likely to bleed earlier in the course of their disease than are cirrhosis patients without portal vein thrombosis. Cirrhosis patients with portal vein thrombosis also tolerate portosystemic shunting better than most others do because the hepatic artery supplies virtually all of their hepatic blood flow so that their hepatic hemodynamics are unaffected by portal venous diversion surgery. Less common causes of portal vein thrombosis are Budd-Chiari syndrome, congestive heart failure, intravascular invasion by primary or secondary neoplasms of the liver, cytomegalovirus infection, and Behçet's disease. The incidence of portal vein thrombosis in hepatocellular carcinoma is 26% to 34%, but at autopsy, tumor invasion of portal vein branches is seen in 70% and hepatic vein involvement in 13% of cases. Portal vein thrombosis has been detected sonographically in 8% of patients with liver metastases. For detection of venous invasion in patients with hepatocellular carcinoma, sonography has a sensitivity of 64% and specificity of 98% compared with arterial portography.⁵⁸⁻⁶⁰

Myeloproliferative disorders and blood dyscrasias account for approximately 12% to 48% of cases of portal vein

thrombosis. Portal hypertension, from whatever cause, is also a major risk factor in the development of portal vein thrombosis.⁵⁸⁻⁶⁰

RADIOLOGIC FINDINGS

Plain Radiography

Calcification can occasionally be seen on plain abdominal radiographs in either the portal vein thrombus or the wall of the portal vein. The calcium is deposited diffusely in the clot, whereas mural calcifications are seen as parallel, discontinuous, radiodense lines directed along the course of the portal vein. Plain radiographs may reveal ileus, a localized sentinel loop, or, if the gut is ischemic or infarcted, thumbprinting caused by submucosal edema and hemorrhage.

Ultrasound

Failure to identify the portal vein is a significant finding and virtually diagnostic of portal vein occlusion. Ultrasound is the primary imaging modality for diagnosis and follow-up of portal vein thrombosis because of its ease of execution, sensitivity (particularly combined with color Doppler studies), lower cost, and availability and because it does not require use of intravenous contrast material. On sonographic evaluation (Fig. 90-22), portal vein thrombosis is manifested as an intraluminal echogenic reflector that can partially or completely fill the vein, obscuring normal portal vein landmarks. The portal vein may be expanded in acute thrombosis or when a neoplasm is present. Small sonolucencies may be present within tumor thrombus, but in most cases, bland thrombus cannot be differentiated from tumor thrombus. Tumor thrombosis can be differentiated from bland thrombus by demonstrating color Doppler flow and arterial waveforms (often hepatofugal in direction) within the tumor thrombus on duplex Doppler examination. Lack of flow does not exclude tumor thrombus. Pulsatile flow is fairly specific for malignant thrombus. In these patients, the hepatic artery is dilated with increased systolic central streamline flow.

Figure 90-22 Portal vein thrombosis: sonographic findings.

Tumor thrombus is present in the main portal vein in this patient with hepatocellular carcinoma. Arterial color flow signal is identified within the thrombus.

In these cases, fine-needle aspiration under sonographic guidance identifies or excludes tumor. The superior mesenteric and splenic veins may dilate proximal to the thrombus as well. Although the sonographic appearance of tumor thrombus is nonspecific, neoplastic obstruction is often fairly obvious because the offending hepatic or pancreatic mass is usually quite large.⁶¹⁻⁶⁶

Duplex Doppler imaging has a sensitivity of 100% and specificity of 93% in detecting thrombus of the main portal vein.⁶¹⁻⁶⁶ The diagnosis of intrahepatic portal vein thrombus is more difficult to establish confidently because of the high background echogenicity of the liver. Color flow Doppler sonography offers several distinct advantages over conventional spectral Doppler: it passively and automatically depicts blood flow in real time; it permits quick diagnosis of abnormal hepatofugal flow; it can reveal flow and collaterals that are invisible on gray-scale images; and it can allow diagnosis of potentially confusing helical blood flow.

In chronic thrombosis, the portal vein can be normal sized or small, and bridging collaterals may develop in the porta hepatis, particularly when thrombus occurs early in life. These vessels are often prominent in cavernous transformation of the portal vein, which occurs in 30% of patients with portal vein occlusion.⁶¹⁻⁶⁶ Doppler examination shows a typical continuous, low-frequency portal venous flow pattern in these vessels. Secondary sonographic signs of portal vein thrombosis include splenomegaly, ascites, venous collaterals, and mesenteric vein thrombosis causing intestinal congestion or infarction. Serial scans are useful in these patients to determine the efficacy of therapy or to monitor the development of cavernous transformation after acute portal vein thrombosis.

Sonographic demonstration of normal portal and splenic vein diameter and normal vascular caliber variation during respiration excludes the diagnosis of portal vein occlusion with a high level of certainty. Ultrasound can also distinguish between tumor extension into the portal vein and extrinsic portal compression in cases of malignant disease.

Computed Tomography

Portal vein thrombosis appears as a low-density central zone surrounded by an intensely enhanced periphery on contrast-enhanced scans (Figs. 90-23 and 90-24). It is not entirely clear whether this peripheral enhancement is due to flow around the clot or enhancement of the vasa vasorum of the portal vein wall. There is also transient inhomogeneous enhancement of the periportal hepatic parenchyma. Enlargement of the occluded vein increases the likelihood of the presence of tumor thrombus. There may also be streaky enhancement of the clot, which correlates with the angiographic finding of “threads” with septic thrombophlebitis and “streaks” seen in tumor thrombus (Fig. 90-25; see also Fig. 90-22). On precontrast scans, the portal vein contents may be high in attenuation because of the high protein content of concentrated red blood cells.⁶¹⁻⁶⁶

A number of indirect signs of portal vein thrombosis are related to alterations in segmental hepatic blood supply. Portions of liver that experience segmental portal vein occlusion appear atrophic and have decreased attenuation on noncontrast scans. This appearance is caused by fatty infiltration secondary to nutritional ischemia. Decreased parenchymal enhancement is also identified in the lobe involved by portal vein thrombosis. Increased arterial flow may be identified when scans are obtained during the arterial phase.⁶¹⁻⁶⁶

Figure 90-23 Portal and superior mesenteric vein thrombosis: CT findings. **A.** Coronal, reformatted MDCT image shows thrombus (arrow) in the main portal vein in this patient with a coagulopathy. **B.** Coronal reformatted image, anterior to **A**, demonstrates the thrombus extending into the superior mesenteric vein and its branches.

Figure 90-24 Septic intrahepatic portal vein thrombosis: CT and MR findings. Coronal CT (**A**) and MR (**B**) reformatted images show thrombus (red arrow) within an intrahepatic right portal vein. Infection in the liver (yellow arrows) peripheral to this infected thrombus is also present. There is a small amount of ascites.

Arterioportal shunting is another indirect sign of portal vein obstruction. In these cases, enhancement of the involved portal vein branch occurs early in the arterial phase. Calcification of the portal vein thrombus is also readily detected by CT.

On CT scans, portal vein thrombosis may simulate other disorders: gas in a collateral periportal vein can mimic an abscess; expansion of a thrombus-filled inferior mesenteric vein may resemble a pancreatic neoplasm or pseudocyst; segmentally occluded portal veins may simulate dilated bile ducts; and multiple intrahepatic stones may mimic calcified portal vein thrombus.

Magnetic Resonance Imaging

MRI is another excellent means of demonstrating portal vein thrombosis (Figs. 90-26 and 90-27).⁶¹⁻⁶⁶ The appearance of the

clot on MR images depends on its age, oxidation state of hemoglobin, thrombus composition, organization in the thrombus, and field strength. Acute thrombus (<5 weeks old) appears hyperintense relative to muscle and liver on both T1-weighted and T2-weighted images. Older thrombi (between 2 and 18 months) appear hyperintense relative to liver but only on T2-weighted images. Tumor and bland thrombus can be distinguished by the fact that tumor thrombus has a higher signal intensity on T2-weighted images, is soft tissue signal intensity on time-of-flight gradient-echo images, and enhances with gadolinium. Bland thrombus, by contrast, has a low signal intensity on T2-weighted and time-of-flight gradient-echo images and does not enhance with gadolinium. In patients with infected bland thrombus, increased enhancement of the vein wall may be identified.

Intrahepatic portal vein occlusion can produce triangular, wedge-shaped regions in the liver that show high signal intensity on T2-weighted images and on immediate postgadolinium spoiled gradient-echo images. The apex of this region is central, and the base abuts the liver capsule. These changes are presumably due to infarction or edema of the involved hepatic segment.⁶¹⁻⁶⁶

Figure 90-25 Portal vein tumor thrombus: CT features. There is direct visualization of arterial neovascularity in tumor thrombus, producing a "streaks and threads" (arrows) appearance. (Case courtesy Richard L. Baron, MD, Chicago, Ill.)

As noted with CT, after the intravenous administration of gadolinium, transient increased enhancement of hepatic parenchyma may become evident in areas of decreased portal perfusion during the capillary phase of enhancement. Regions with absent or diminished portal blood supply have a commensurate increase in hepatic arterial blood supply. This autoregulatory mechanism provides that areas affected by portal vein thrombosis and increased arterial blood supply enhance intensely because the gadolinium delivered in the first phase is more concentrated in hepatic arteries than in portal veins and is delivered earlier by hepatic arteries than by portal veins. As the concentration of gadolinium in the hepatic arteries and portal veins equilibrates, this differential enhancement disappears.

Figure 90-27 Portal vein thrombosis: MRI findings. Coronal image shows thrombus (arrow) in the main portal vein.

Figure 90-26 Intrahepatic portal vein thrombosis: MRI findings. **A.** Contrast-enhanced multiplanar reconstruction of SD-LAVA sequence shows thrombosis of the intrahepatic portion of the right hepatic vein (arrow). **B.** Thin-slab maximum intensity projection three-dimensional gradient-echo image shows the portal vein thrombus and early venous recanalization (arrow). (Case courtesy Roberto Schuman, MD.)

TREATMENT

Traditionally, the treatment of portal vein thrombosis has been based on early surgical and anticoagulant therapy. A number of percutaneous procedures in which the thrombosis is treated by angioplasty or is lysed by direct urokinase infusion have been reported.

The surgical approach has two major difficulties: the collateral veins are often not sufficiently large to allow a bypass procedure to be performed, and there is an increased incidence of shunt thrombosis and obstruction when a bypass procedure is performed. Therefore, medical management is preferred unless hemorrhage cannot be controlled or there are repeated life-threatening bleeds.⁶¹⁻⁶⁶

Cavernous Transformation of the Portal Vein

Cavernous transformation of the portal vein (CTPV) develops when small collateral veins near the edge of the portal vein dilate, expand, and effectively replace the obliterated portal vein as the major hepatopetal venous conduit. These numerous wormlike vessels at the porta hepatis represent periportal collateral circulation. This transformation develops in long-standing thrombosis, requiring 12 months to occur, and thus more commonly is found in benign disease. This remarkable collateral development reflects the body's effort to maintain hepatopetal portal flow to the liver in the face of occlusion of the extrahepatic portal veins. Collaterals of this magnitude do not typically develop in cirrhotic patients because intrahepatic portal resistance is high in cirrhosis.⁶⁷⁻⁶⁹

In patients with CTPV, sonograms show a mass of tubular anechoic collaterals (Fig. 90-28). Normal portal venous landmarks are obliterated. Doppler evaluation of these collaterals shows a slightly turbulent low-velocity venous signal with little or no respiratory or cardiac variation. It is hepatopetal in direction and has portal venous waveform. Associated findings include splenomegaly, thickening and varices of the lesser omentum, spontaneous splenorenal shunts, and gallbladder varices.

On CT (Fig. 90-29) and MRI (Fig. 90-30), CTPV appears as contrast medium-filled portal collaterals in the hepatoduodenal ligament. In addition, compensatory arterial blood flow in these patients may produce a peculiar enhancement pattern.

CTPV induces morphologic changes in the liver, the most common being atrophy of the right hepatic lobe and left lateral segment and hypertrophy of liver segment IV and the caudate lobe. It is postulated that segment IV and the caudate lobe become hypertrophic with CTPV because of their proximity to the cavernous transformation, which results in maintained portal inflow. Similarly, the right liver lobe and the left lateral segment become atrophic with CTPV because of their greater distance from the cavernous transformation, which leads to compromised portal venous flow.⁶⁸

Figure 90-28 Cavernous transformation of the portal vein: sonographic features. Color Doppler scan shows multiple collateral vessels in the portal vein.

Figure 90-29 Cavernous transformation of the portal vein: CT features. Three-dimensional shaded surface coronal (A) and axial (B) MDCT images show multiple enhancing tubular structures (circle) in the hepatoduodenal ligament.

Figure 90-30 Cavernous transformation of the portal vein: MRI features. Coronal MR portogram shows multiple dilated collaterals (arrow) in the hepatoduodenal ligament and dilation of the superior mesenteric vein.

Superior Mesenteric Vein Thrombosis

Isolated superior mesenteric vein (SMV) thrombosis accounts for only 5% to 15% of all intestinal vascular thromboses, being less common than arterial occlusion. It is most common in patients in their 50s and 60s, and 81% of patients have associated illnesses.⁷⁰⁻⁷³

CLINICAL FINDINGS

SMV thrombosis can be classified into acute and chronic presentations for the purposes of management. In acute thrombosis, the patients present with symptoms of less than 4 weeks' duration. The patient has pain out of proportion to the physical findings, nausea, and vomiting, with or without bloody diarrhea. Most cases are associated with metabolic acidosis and mild to moderate leukocytosis. Venous thrombosis occurs in patients younger than those with arterial thrombosis.⁷⁰⁻⁷³

Chronic mesenteric thrombosis is difficult to detect as the onset is insidious and patients are asymptomatic until late complications occur, such as variceal bleeding due to portal hypertension. The patients may present with weight loss, food avoidance, postprandial pain, or distention.⁷⁰⁻⁷³

PATHOPHYSIOLOGY

The causes of isolated SMV thrombosis include myeloproliferative disorders, peritonitis and inflammatory disorders of the abdomen, tumor compression, portal hypertension, the postoperative state, hypercoagulable states (antithrombin III and

protein C and protein S deficiencies), Weber-Christian disease, blood dyscrasias, and pancreatic neoplasms. Extensive venous collaterals in the gut prevent infarction in most cases of SMV thrombosis, so that the mortality rate is only 20%, lower than the 40% to 60% rate for arterial occlusion.⁷⁰⁻⁷³

RADIOLOGIC FINDINGS

Plain film findings are usually noncontributory and may show only ileus. Pneumatosis intestinalis can be seen if the bowel is infarcted, and ascites may develop in patients with chronic SMV thrombosis. Bowel wall thickening and mucosal irregularity indicate intestinal ischemia. On CT scans, the SMV thrombus (Fig. 90-31) appears as a low-density intraluminal mass with a hyperdense periphery, as is seen in portal vein thrombosis. If there is intestinal ischemia as well, mural thickening of the gut may also be seen. Selective angiography usually shows spasm of the superior mesenteric artery (SMA) and no opacification of the affected veins in the venous phase.

Ultrasound is effective in allowing diagnosis of splanchnic vein thrombosis, but if there is no associated portal vein thrombus, the diagnosis of SMV thrombosis is much more difficult, particularly in patients with a gassy abdomen. The gray-scale and Doppler characteristics of SMV thrombus are similar to those seen in the portal vein. Similarly, the CT and MRI findings are identical to those of portal vein thrombosis.

TREATMENT

Small bowel resection in patients with SMV thrombosis is associated with high rates of morbidity and mortality, so that conservative management is indicated when there are no signs of intestinal ischemia or infarction. Direct infusion of fibrinolytic agents into the mesenteric-portal system has been suggested as an alternative treatment in mesenteric vein occlusion. In this procedure, access to the portal system is gained under sonographic guidance, as in percutaneous transhepatic portography, and a large dose of urokinase is infused.⁷⁰⁻⁷³

Splenic Vein and Inferior Mesenteric Vein Thrombosis

Splenic vein occlusion is usually a result of pancreatitis, pancreatic carcinoma, lymphoma, or propagation of clot from the portal vein. Chronic pancreatitis accounts for 65% of all cases of splenic vein thrombosis.⁷⁴⁻⁷⁷ This condition is often clinically silent, but it may cause localized venous hypertension that can result in splenomegaly and bleeding gastric varices. Splenic vein thrombosis should be suspected in patients with splenomegaly and a history of gastrointestinal hemorrhage with normal liver function test results. Other causes include sclerotherapy, splenectomy, and the causes of portal vein and SMA thrombosis.

Splenic vein occlusion produces rerouting of venous flow through the short gastric veins and gastroepiploic vein, causing "left-sided" portal hypertension. Gastric varices in the cardia and fundus are seen in 74% to 83% of patients with splenic vein occlusion.⁷⁴⁻⁷⁷ They appear as broad, serpentine, redundant filling defects or clusters of polypoid defects, simulating thickened rugal folds. These represent the short gastric, gastroepiploic, and left gastric veins that drain retrogradely into the portal vein. Diagnosis is difficult because they are located

Figure 90-31 Superior mesenteric vein thrombosis. **A.** Sagittal reformatted MDCT image shows thrombus (arrow) in the superior mesenteric vein in this patient with a coagulopathy. **B.** Coronal reformatted image shows edema in the small bowel mesentery (yellow arrow) and mural thickening of the small bowel (blue arrow) due to mesenteric ischemia.

Figure 90-32 Splanchnic venous thrombosis. **A.** Low-density thrombus (arrow) is present within the splenic vein propagating into the portal vein in this patient with a coagulopathy. **B.** Inferior mesenteric vein thrombus (arrow) is depicted on this coronal reformatted CT image in a patient with diverticulitis.

primarily in the subserosa. The appearance of thrombus on CT (Fig. 90-32A), ultrasound, and MRI studies in splenic vein thrombosis is identical to that observed in portal vein or SMV thrombosis. Isolated gastric varices of the short gastric and coronary vessels without esophageal varices were thought to be highly suggestive of splenic vein obstruction; however, one study has demonstrated that portal hypertension is still the most common underlying cause.⁷⁴⁻⁷⁷ Dilation of the gastroepiploic veins is seen only in splenic vein thrombosis.

Splenic vein thrombosis secondary to pancreatitis is now recognized as a fairly common cause of upper gastrointestinal hemorrhage in these patients. For this problem, splenectomy and gastrotomy with oversewing of bleeding varices is sufficient treatment.⁷⁴⁻⁷⁷ Isolated gastric varices caused by splenic vein occlusion can be cured in 90% of cases, and the incidence of recurrent bleeding is low.⁷⁴⁻⁷⁷

Thrombus in the inferior mesenteric vein (Fig. 90-32B) is usually seen in the setting of diverticulitis.

Hepatic Infarction

CLINICAL FINDINGS

Hepatic infarction is a relatively uncommon occurrence because of the liver's dual blood supply and the tolerance of hepatocytes for low oxygen saturation. Hepatic infarction has been associated with shock (Fig. 90-33), sepsis, anesthesia, oral contraceptives, sickle cell disease or trait, polyarteritis nodosa, eclampsia, metastatic carcinoma, bacterial endocarditis, arterial emboli in rheumatic heart disease, trauma, and intra-arterial hepatic chemotherapy. The incidence of ischemic hepatitis in cirrhotic patients admitted to the intensive care unit with variceal bleeding is reported to be as high as 9% with a 60% mortality.⁷⁸⁻⁸⁰

The clinical diagnosis is problematic. Patients usually present with the nonspecific findings of abdominal or back pain (or both), fever, leukocytosis, and abnormal liver function test results, but they may be relatively asymptomatic.

PATHOLOGIC FINDINGS

Ischemic hepatitis is usually diagnosed on the basis of characteristic hepatic histopathologic appearance: minimal centrilobular necrosis and seronegativity for viral hepatitis.

RADIOLOGIC FINDINGS

It is difficult to detect hepatic infarction during its early stages by cross-sectional imaging. The region becomes sonographically hypoechoic when there is sufficient edema and round cell infiltration with indistinct margins. As the necrotic tissue is resorbed, small bile duct cysts or lakes may form. These lakes have the same microscopic appearance as the cysts seen in Caroli's disease, suggesting that the cause of Caroli's disease may actually be neonatal hepatic infarction. On occasion, large bile duct lakes can be seen on CT and ultrasound studies. Infarcts are usually well-circumscribed, peripheral, wedge-shaped lesions, but they can be round or oval and centrally located. With time, areas of infarction develop a more distinct margin and may undergo considerable atrophy. Not all wedge-shaped areas of decreased attenuation on CT scans are due to infarction; decreased portal flow from thrombus, tumor compression,

Figure 90-33 Hepatic infarction: pathologic findings. Autopsy specimen from a patient who died of septic shock shows multiple regions of hemorrhage within the liver.

or segmental hepatic vein obstruction may produce a similar picture. Gas formation within a sterile infarct can also be seen on CT (Fig. 90-34) and ultrasound studies. On MR images, the edema of infarction lengthens T1 and T2 relaxation times, causing lower signal intensity on T1-weighted images and higher signal intensity on T2-weighted images of the involved liver.⁷⁸⁻⁸⁰

Hemolysis, Elevated Liver Enzymes, Low Platelets (HELLP) Syndrome

Hepatic ischemia, hemorrhage, and infarction are well-known complications of pregnancy-related HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. It is a variant of toxemia that occurs either ante partum or post partum and develops in 4% to 12% of patients with severe preeclampsia.⁸¹⁻⁸³

The pathophysiologic mechanism of HELLP syndrome is related to endothelial damage in the placental bed, resulting in activation of the platelets, which causes them to aggregate, and the coagulation cascade, which leads to disseminated intravascular coagulation. The hemolytic anemia is due to passage of red blood cells through small vessels with damaged endothelium covered by fibrin. Fibrin deposition in the liver leads to hepatocellular damage, necrosis, and hemorrhage.

Epigastric or right upper quadrant pain is found in 90% of patients and may be associated with malaise, nausea, vomiting, headache, and nasal bleeding.⁸¹⁻⁸³ Confirmatory laboratory data include hemolytic anemia (hemoglobin <11 g/dL), elevated liver enzymes (lactate dehydrogenase >400 IU/L), and thrombocytopenia (<100,000/mL).⁸¹⁻⁸³

The clinical course of HELLP syndrome is variable. Important complications include massive liver cell necrosis, severe

Figure 90-34 Hepatic infarction: CT features. Gas secondary to infarction is present within the lateral segment of the left lobe of the liver in this patient who had undergone a Whipple procedure 5 days before this study.

disseminated intravascular coagulation, abruptio placentae, renal failure, pulmonary edema, maternal hypoglycemia, and rupture of subcapsular hematoma, with a maternal mortality rate of 3.3%. Standard treatment consists of expeditious delivery of the fetus.⁸¹⁻⁸³

Imaging studies are usually performed in these patients to determine the cause of the abdominal complaints. On sonographic evaluation, the portions of the liver undergoing necrosis have increased echogenicity. CT scan reveals well-defined hypodense, nonenhancing areas or multiple peripheral wedge-shaped areas of low attenuation (Fig. 90-35). The CT and ultrasound appearance in these patients is nonspecific and can mimic focal areas of fatty infiltration.^{84,85}

The MRI appearance in the HELLP syndrome depends on the degree of hemorrhage, necrosis, and steatosis. When edema or cellular necrosis predominates, the affected areas have a low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.^{84,85}

Figure 90-35 HELLP syndrome. This pregnant patient presented with acute abdominal pain, hemolysis, elevated liver enzymes, and low platelets (HELLP). **A.** CT scan shows hepatic hemorrhage with active extravasation of contrast material from multiple sites. Hypodense areas are also present, suggesting thrombosis. **B.** CT scan obtained at a lower level shows the fetus.

Visceral Artery Aneurysms

CLINICAL FINDINGS

Splenic artery aneurysms (Fig. 90-36A) account for 60% of visceral artery aneurysms, followed by the hepatic artery (20%), SMA (5.5%), celiac artery (4%) (Fig. 90-36B), gastric and gastropiploic arteries (4%), jejunal, ileal, and colic arteries (4%), pancreaticoduodenal and pancreatic arteries (2%), gastroduodenal artery (1.5%), and inferior mesenteric artery (<1%).⁸⁶⁻⁹⁵

The splenic artery is a tortuous structure because of the movement of the spleen and differing volumes of blood needed to supply it. The pulsatile nature of the blood flow causes excess stretching of the artery, thereby causing the loops and bends seen angiographically and on cross-sectional imaging; and various branches of the splenic artery that supply the pancreas anchor and prevent the elongating splenic artery from forming one large loop instead of multiple, small excursions from the

Figure 90-36 Visceral artery aneurysms. **A.** CT angiogram shows an aneurysm (arrow) of the superior mesenteric artery. **B.** Aneurysm (circle) of the splenic artery.

direct path. The dilated, tortuous splenic artery protects the delicate splenic pulp so that pressures are less forceful and more indirect.⁸⁷

Splenic artery aneurysms are four times more common in women than in men, and most are small (2-4 cm), asymptomatic, solitary, saccular, and located in the middle to distal splenic artery. There is also an association of splenic artery aneurysm and pregnancy, parity, and portal hypertension. This female predilection likely relates to the hormonal effect of estrogen and progesterone, both with receptor sites in the arterial wall. The hormone relaxin, which is responsible for elasticity of the symphysis pubis in late pregnancy, may also alter the elasticity of the arterial wall. The high flow rate associated with pregnancy and portal hypertension contributes to the deleterious effects on the arterial wall.⁸⁶⁻⁹⁵

Rupture is a catastrophic event that is manifested with pain and hypotension. Impending rupture of a splenic artery aneurysm can produce left upper quadrant pain that radiates to the left subcapsular region. In 20% to 30% of patients, there is double rupture: the initial rupture is contained within the lesser sac, followed by penetration of the lesser sac and free rupture into the peritoneal cavity. Rupture of a splenic artery aneurysm, most common during the third trimester, is a catastrophic event, with reported maternal and fetal mortality rates of 70% and 90%, respectively.⁸⁶⁻⁹⁵

Ruptured and symptomatic splenic artery aneurysms require treatment, as do those found in pregnant women and women of childbearing age. Patients with portal hypertension or those who undergo liver transplantation are also candidates for treatment. Enlarging aneurysms and those larger than 2.5 to 3.0 cm typically require treatment.⁸⁶⁻⁹⁵

Hepatic artery aneurysms show a male predilection of 2:1. Most are solitary and involve the extrahepatic artery, in which case they are most often degenerative or dysplastic. Intrahepatic hepatic artery aneurysms are most frequently the result of trauma, iatrogenic injury from biopsy or intervention, infection, or vasculitis. The use of MDCT has resulted in an increased detection of post-traumatic false aneurysms of the intrahepatic arterial branches. Approximately 60% of hepatic artery aneurysms are symptomatic, and patients most often present with epigastric or right upper quadrant pain, followed in frequency by gastrointestinal hemorrhage and jaundice.⁸⁶⁻⁹⁵ The classic triad of abdominal pain, hemobilia, and obstructive jaundice is observed in only 30% of cases.⁸⁶⁻⁹⁵ When these findings are accompanied by an abdominal bruit or pulsatile mass, the diagnosis of hepatic artery aneurysm should be suspected. The aneurysm may rupture into the peritoneal cavity, extrahepatic bile duct, duodenum, gallbladder, portal vein, or stomach. Obstructive jaundice may result from intrabiliary clots or from extrinsic compression. The mean age at diagnosis is 38 years, and a twofold to threefold male predominance is observed. Extrahepatic aneurysms are four times more common than intrahepatic aneurysms. It is essential to diagnose and to treat hepatic artery aneurysms because of the high incidence of rupture and an associated mortality of up to 82% when this occurs.⁸⁶⁻⁹⁵

Aneurysms and pseudoaneurysms of the gastroduodenal and pancreaticoduodenal arteries are often complications of acute and chronic pancreatitis and pancreatic surgery. Most of these aneurysms are symptomatic and are manifested with gastrointestinal, intraperitoneal, or retroperitoneal hemorrhage.

Aneurysms of the SMA account for 5.5% of all visceral artery aneurysms and can be saccular or fusiform. Most occur within

the proximal 5 cm of this vessel. Most occur in men and are most often diagnosed in the fifth decade of life. These aneurysms may be mycotic in origin or secondary to inflammation, vasculitis, trauma, arterial dissection, and dysplasia and degeneration. These aneurysms are often symptomatic, presenting with acute and colicky upper abdominal pain, nausea, and vomiting.⁸⁶⁻⁹⁵

Celiac artery aneurysms account for 4% of all visceral artery aneurysms and are associated with abdominal aortic aneurysms in 20% of cases and other visceral artery aneurysms in 40%. There is no gender predilection, and most present in the fifth decade of life. The risk of rupture is approximately 13% with high mortality.

In early studies, rupture of visceral artery aneurysm was reported in 22% of cases.⁸⁶⁻⁹⁵ Now a large number are discovered incidentally when the patient is being scanned for other reasons. Indeed, the routine use of MDCT and MRI has led to the increased diagnosis of both symptomatic and asymptomatic aneurysms. Most are degenerative, demonstrating deficiency of the arterial media. Pancreatitis with the escape of pancreatic enzymes may promote destruction of the arterial wall, resulting in pseudoaneurysms of the splenic, hepatic, gastroduodenal, and pancreaticoduodenal arteries. These aneurysms can be treated with surgical or endovascular approaches.

RADIOLOGIC FINDINGS

Hepatic artery aneurysms may produce curvilinear calcification of the right upper quadrant and, when large, produce a mass effect on adjacent viscera on barium studies or on the bile ducts on cholangiograms. Duplex and color flow Doppler studies are the noninvasive screening methods of choice for hepatic artery aneurysm. A pulsatile, cystic mass with arterial flow or a sonolucent or mixed echogenic mass with dilation of ducts proximally suggests the diagnosis. Noncontrast CT may show aneurysm wall calcification. After the bolus administration of contrast material, the residual lumen demonstrates intense enhancement. A low-density thrombus is often seen peripherally. MRI demonstrates a tubular structure that has flow void or strong signal intensity, depending on the imaging sequence used. These aneurysms must be differentiated from pancreatic pseudocysts and cystic pancreatic neoplasms.

Treatment of these lesions is either surgical (ligation or vein grafting) or angiographic (absorbable gelatin foam plugs for small aneurysms and Gianturco coils for larger ones). Invasive radiographic methods are becoming increasingly popular because of the high morbidity and mortality associated with surgery. Reconstructive or ablative surgery is indicated for extrahepatic aneurysms, whereas interventional techniques are favored for those in intrahepatic sites.

Aneurysms of the SMA are rare and may be congenital or associated with pancreatitis, trauma, neoplasm, mycoses, or atherosclerotic disease. They are manifested clinically as a pulsatile mass with a systolic bruit. SMA aneurysms may be saccular or fusiform and are also always located within the first 5 cm of the SMA. The SMA is the most common site for infection of a peripheral muscle artery, which most often occurs secondary to subacute bacterial endocarditis caused by nonhemolytic streptococcal infection. Almost all patients are younger than 50 years. During the previous four decades, infected aneurysms accounted for 58% to 63% of all SMA aneurysms. In the past decade, this has decreased to 33% of reported aneurysms.⁸⁶⁻⁹⁵

This decrease has been accompanied by an increase in the incidence of true aneurysms in the elderly as well as an increase in the incidence of false aneurysms associated with inflammatory processes of the pancreas and biliary tract seen in 12% of SMA aneurysms. Dissection, although uncommon, affects the SMA more than any other visceral artery. Atherosclerosis is present in 25% of reported SMA aneurysms.⁸⁶⁻⁹⁵

In contrast to other visceral artery aneurysms, most SMA aneurysms are symptomatic, presenting with moderate to severe abdominal pain that is usually progressive in its course. A palpable mass is present in 50% of patients, who may also experience nausea, vomiting, gastrointestinal hemorrhage, hemobilia, or jaundice.⁸⁶⁻⁹⁵

Splanchnic Vein Aneurysms

Aneurysms of the portal venous system are uncommon. They represent only 3% of all aneurysms of the venous system but are the most common visceral aneurysms.⁹⁶⁻¹⁰⁴ Because there are variations in the diameters in normal and cirrhotic livers, an aneurysm of the portal venous system is present if the vessel diameter is larger at that point (usually 2 cm) than in the remainder of the vessel. They are usually secondary to pancreatitis and trauma but may be congenital in origin and are seen increasingly in patients with cirrhosis and portal hypertension.

The clinical features of portal vein aneurysms vary. Large aneurysms can cause duodenal compression, common bile duct obstruction, or chronic portal hypertension. Complete obstruction of the portal vein by thrombosis or aneurysm rupture can also occur. Patients who have no symptoms and no signs of portal hypertension should be observed by serial ultrasound scans. Complications of portal vein aneurysms include rupture, thrombosis, complete occlusion of the portal vein, portosystemic shunts, and biliary tract compression.

On ultrasound (Fig. 90-37) and CT studies, a dilated portal vein can usually be identified and distinguished from other lesions. The aneurysm is anechoic, but if thrombus is present, Doppler studies are necessary for confirmation. On Doppler ultrasound, constantly rotating blood is found in an aneurysm of the splenic vein and SMV. Contrast-enhanced CT and MRI will show robust enhancement of the aneurysm.

Osler-Weber-Rendu Disease

Osler-Weber-Rendu disease or hereditary hemorrhagic telangiectasia (HHT) is a rare (incidence of 1 to 2 : 100,000) autosomal dominant disorder characterized by multiple mucocutaneous telangiectasias that may involve most organ systems.¹⁰⁵⁻¹¹¹ Hepatic involvement is frequent and is usually diagnosed 10 to 20 years after the first appearance of mucocutaneous telangiectasias. The typical pathologic features are angiodyplastic vascular changes, including telangiectases, cavernous hemangiomas, aneurysms of the intraparenchymal branches of the hepatic artery, and both hepatoportal and hepatohepatic arteriovenous fistulas. Many patients develop high-output heart failure as a result of left-to-right intrahepatic shunts.

On Doppler ultrasound examinations in patients with HHT, the spectral waveforms show high-velocity flow (153 cm/s) in the dilated and tortuous hepatic artery and its branches. Hepatic artery-to-portal vein shunts cause pulsatility of portal flow with phasic or continuous reversal. Hepatic artery-to-hepatic

Figure 90-37 Umbilical vein aneurysm. Color Doppler ultrasound shows flow in this venous aneurysm.

vein shunts cause significant changes in the Doppler waveform of the hepatic vein only in severe stages of the disease. Color Doppler sonography demonstrates a large arteriovenous malformation or tangled masses of enlarged tortuous arteries or multiple aneurysms of the hepatic arterial branches within the liver.¹⁰⁵⁻¹¹¹

Contrast-enhanced CT (Fig. 90-38) shows a prominent extrahepatic or both extrahepatic and intrahepatic hepatic artery that is often associated with dilated hepatic or portal veins. Early filling of the portal venous or hepatic venous trunks on helical CT indicates the presence of an arteriovenous shunt. The intrahepatic arteriovenous fistulas are being visualized with increased frequency with the use of MDCT. Other abnormalities include telangiectasias, large confluent vascular masses, and transient hepatic attenuation differences.¹⁰⁵⁻¹¹¹

MR angiograms can provide a map of the anomalous vessels. Dynamic gradient-echo imaging obtained after the injection of Gd-DTPA allows analysis of filling kinetics.

Angiograms in HHT show tortuous dilated hepatic arteries, diffuse telangiectases with a diffuse mottled capillary blush, hemangiomas, and early filling of hepatic or portal veins indicating a shunt. The angiographic appearance depends on the stage of development of the hepatic arteriovenous shunt. All findings are present if the shunting is severe, whereas isolated parenchymal modifications are found only in the case of a mild intrahepatic shunt.

Figure 90-38 Osler-Weber-Rendu disease: CT features. **A.** Arterial phase axial CT image shows irregular and tortuous arteries in the liver parenchyma and porta hepatis. **B.** Coronal maximum intensity projection reconstructed image in arterial phase demonstrates tortuous and irregular arteries in liver and porta hepatis.

Hepatopulmonary Syndrome

The hepatopulmonary syndrome (HPS) describes the clinical relationship between hepatic dysfunction and the presence of pulmonary vascular dilations, which can result in a range of arterial oxygenation abnormalities. HPS can be defined as a triad characterized by severe parenchymal liver disease, hypoxemia (an increased alveolar-arterial gradient on breathing of room air), and evidence of intrapulmonary vascular dilations.¹¹²⁻¹¹⁵

PATHOPHYSIOLOGY

A number of mechanisms underlying the impaired gas exchange in HPS have been proposed: intrapulmonary and porto-pulmonary shunts, pleural spiders, pulmonary hypertension, ventilation-perfusion mismatch, and changes in the affinity of hemoglobin for oxygen.¹¹²⁻¹¹⁵ It now appears that vascular abnormalities known as intrapulmonary vascular dilations are the major cause of severe hypoxemia and are the defining features of HPS (Fig. 90-39A).

IMAGING OF INTRAPULMONARY VASCULAR DILATIONS

Contrast-Enhanced Echocardiography

Contrast-enhanced echocardiography, although generally used to assess intracardiac right-to-left shunts, is valuable for demonstrating the presence of intrapulmonary vascular dilations in patients with hypoxemia and liver disease. Indocyanine green dye and agitated saline are used to provide a stream of microbubbles 60 to 90 μ m in diameter that usually opacify only the right chambers of the heart. The normal pulmonary capillary bed filters these microbubbles so that they do not appear in the left side of the heart. In the presence of an intracardiac or intrapulmonary shunt, microbubbles and indocyanine dye opacify the left-sided heart chambers.

Intracardiac intrapulmonary shunts can be differentiated by the timing of the appearance of left-sided bubbles after injection of the contrast agent. With intracardiac right-to-left shunts, microbubbles and dye are visualized within three heartbeats after the appearance of bubbles in the right-sided heart chambers. In intrapulmonary shunts, the appearance of contrast

material in the left-sided heart chambers is delayed, occurring four to six heartbeats after the initial appearance of contrast material in the right side of the heart.¹¹²⁻¹¹⁵

Perfusion Lung Scanning

The perfusion lung scan (Fig. 90-39B) with technetium Tc 99m-labeled macroaggregated albumin is the second major method for detecting intrapulmonary vascular dilation. The normal pulmonary capillary bed (diameter, 8-15 μ m) traps the albumin macroaggregates, which generally exceed 20 μ m in diameter. The presence of isotope in the brain or kidneys indicates a right-to-left shunt through either an intracardiac or an intrapulmonary shunt. The shunt magnitude is calculated by taking the ratio of the systemic to total body activity of the isotope. Approximately 3% to 6% of the macroaggregated albumin passes through the normal pulmonary vasculature. Shunts ranging from 10% to 71% have been documented in patients with HPS.¹¹²⁻¹¹⁵

Chest Radiography

Patients with HPS usually display the same abnormalities on the chest radiograph that may be seen in all cirrhotic patients: decreased lung volumes, pleural effusions, increased interstitial markings, and increased pulmonary vascular markings. Increased bilateral basilar interstitial markings attributed to intrapulmonary vascular dilations and increased pulmonary vascular markings may be seen as well. These findings are nonspecific.

CT and Angiography

On CT and angiography, the vascular dilations are depicted as enlarged vessels that do not taper normally, extend to the pleural surface, and are most numerous at the lung bases. The ratio of the segmental arterial diameter to bronchial diameter in the right lower lobe is significantly higher in patients with HPS than in cirrhotic patients with normoxemic liver cirrhosis.¹¹²⁻¹¹⁵

TREATMENT

Treatment of HPS is liver transplantation.^{116,117} If the lungs are irreversibly damaged, a liver-lung transplant is in order. The TIPS procedure has been used as a temporizing measure in patients awaiting transplantation.

Figure 90-39 Hepatopulmonary syndrome: pathophysiology. **A.** Schematic diagram of the precapillary vascular abnormality seen in both acute and chronic liver disorders. The driving pressure of $P_{A_{O_2}}$ is depicted by the arrows. **B.** Pulmonary perfusion images obtained with technetium Tc 99m-labeled macroaggregated albumin show extrapulmonary uptake in the kidneys and brain. This indicates right-to-left shunting.

Hepatic Trauma

Hepatic trauma was first graphically described in the *Iliad*, when Achilles “stabbed with his sword at the liver, the liver was torn from its place, and from it the black blood drenched the fold of his tunic and he was shrouded in darkness as the light went out.” The liver is not faring much better 2600 years later, with the increasing violence of urban life, our society’s passion for high-speed travel, and the gastroenterologist and interventional radiologist constantly invading the liver.¹⁻³ The cross-sectional imaging modalities have dramatically improved the promptness and certainty of diagnosis in patients with hepatic trauma and have proved useful in the triage of patients to surgical or conservative management.⁴⁻⁶ The single most important factor allowing nonoperative management of blunt hepatic trauma has been the evolution of computed tomography (CT) scanning.⁷⁻¹¹

EPIDEMIOLOGY

The types of hepatic injury encountered in practice depend to a large degree on the location of the trauma center. In suburban and rural areas, hepatic injury is usually due to blunt trauma sustained in motor vehicle accidents and falls. In the setting of blunt abdominal trauma, the liver and spleen are the most commonly injured solid organs. The reported prevalence of liver injury in patients who have sustained blunt trauma ranges from 1% to 8%.¹² Other associated injuries are present in 80% of people. In large city hospitals, penetrating injuries from firearms and stabbings predominate. In this setting, the liver is the most frequently injured viscus owing to its anterior and partially subcostal location.^{13,14} Iatrogenic hepatic injuries are becoming increasingly common in all hospitals. Indeed, liver biopsy is the most common cause of subcapsular hematoma in the United States today. Because of their markedly different management paradigms and prognoses, blunt, iatrogenic, and penetrating traumatic injuries are discussed separately in this chapter.

CLINICAL FINDINGS

Clinical features associated with hepatic trauma include right upper quadrant pain and tenderness with guarding and rebound tenderness, falling hematocrit, and hypotension. Delayed manifestations of biliary trauma, such as bilomas, are usually accompanied by right upper quadrant pain and jaundice.^{15,16} Trauma is the most frequent cause of hemobilia, which is manifested by hematemesis or melena associated with right upper quadrant pain. Because of the difficulty of identifying hepatic injury by physical examination, CT is often required to avoid missing a significant injury. The mortality rate reported secondary to blunt liver trauma ranges from 4.1% to 11.7%.^{13,17,18} The American College of Surgeons state a mortality rate of 16.8%, taking all hepatic injuries into account on the basis of the National Trauma Data Bank.^{19,20}

Diagnostic peritoneal lavage was one of the most common clinical modalities used in the diagnostic evaluation for blunt abdominal trauma in the mid-20th century.²¹ This procedure is sensitive for hemoperitoneum but led to a high rate (30%) of nontherapeutic, unnecessary laparotomies. Diagnostic peritoneal lavage has largely been replaced with CT or screening ultrasound for the evaluation of hemoperitoneum.²²⁻²⁴

CLASSIFICATION OF HEPATIC TRAUMA

The management of hepatic trauma patients has evolved significantly during the last three decades and is now based on well-defined treatment algorithms. This has highlighted the need for an accurate classification system as a basis for the clinical decision-making process.²⁵ Fundamental to the development of these classification schemes and the subsequent treatment algorithms based on them is the widespread availability of rapid acquisition CT imaging in most major trauma centers. This has also led to a diminution in the role of diagnostic peritoneal lavage in the management of the trauma patient. Diagnostic peritoneal lavage has multiple limitations: lack of specificity regarding the source of bleeding; high sensitivity to detection of small quantities of blood, leading to nontherapeutic laparotomy; and inaccuracy for retroperitoneal injuries. Diagnostic peritoneal lavage fails most importantly in its ability to identify the location and extent of intra-abdominal organ injury. Diagnostic peritoneal lavage is valuable mainly in patients in whom ultrasonography or CT scanning is inappropriate or unavailable.⁸

Previous attempts to categorize hepatic injury were mostly anatomic in design and did not incorporate the mechanism of injury or physiologic changes associated with more severe injuries. In 1987, the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma was organized for the purpose of devising injury severity scales for individual organs. These injury severity scales incorporated etiology, anatomy, and extent of injury and correlated it with subsequent clinical management and outcome. The most recently revised clinical classification is listed in Table 91-1.²⁶ It has been demonstrated that the CT grade of hepatic injury is not predictive of the need for surgery and that the majority of injuries can be safely managed nonoperatively.²⁶⁻³¹ The hemodynamic status of the patient may be the most important

predictor of injury severity; however, patients with higher grade injuries (IV or V) are more likely to be unstable and to require surgery, and increasing organ injury severity scale grade in patients with isolated hepatic injuries is associated with increasing mortality.⁹ In contrast, patients who are stable may be managed conservatively with close observation in intensive care units.^{8,9,32} Mechanism of injury, radiologic classification, and clinical assessment of hemodynamic stability must all be correlated by the trauma surgeon to guide management decisions.

PATHOPHYSIOLOGY

Blunt Trauma

Approximately 1% to 8% of patients who sustain blunt abdominal trauma have a liver injury.¹² Severe compressive trauma to the liver from a steering wheel injury or direct blow can produce satellite fractures that often involve an entire lobe.³³ Rapid deceleration in motor vehicle accidents produces shearing forces that cause different degrees of parenchymal tears. The hepatic lobes may be torn from each other, or the tears may involve the supporting ligaments, hepatic veins, and inferior vena cava. The most frequent site of hepatic injury is the posterior segment of the right lobe of the liver because of its size and proximity to the ribs and spine. Although they are less common, left lobe injuries are more often associated with retroperitoneal injuries (duodenum and pancreas) and transverse colon injuries.^{30,34} There is a high incidence of associated extrahepatic injury, including splenic rupture, head injuries, rib fractures, facial fractures, and pelvic fractures.³⁵

Major hepatic venous injuries occur in 13% of patients with liver trauma. These are most often a result of blunt trauma. They include, in decreasing order of frequency, right hepatic vein avulsion from the inferior vena cava, upper branch right hepatic vein avulsion, avulsion of accessory veins, avulsion of the left hepatic vein, and avulsion of the middle hepatic vein. The right hepatic vein is at greater risk for sudden acceleration-deceleration injury because it has a relatively long extrahepatic segment before it enters the inferior vena cava. The course is shorter for the middle and left hepatic veins, which usually merge to form a common channel and thus are less frequently injured.^{36,37} Venous injuries can be suggested by multiple lacerations around the inferior vena cava or porta hepatis.^{10,11} It is important to identify these findings because they may help prepare the surgeons to expect significant bleeding when the liver is lifted off the inferior vena cava.¹¹ Multiplanar CT reconstruction and three-dimensional rendering can be helpful in the assessment of vascular involvement, especially the portal vein, hepatic veins, and retrohepatic vena cava.³⁸ Injuries of the bare area of the liver may not demonstrate peritoneal signs or findings on diagnostic peritoneal lavage or screening sonography for hemoperitoneum but may show retroperitoneal blood on CT examination.³⁹

Penetrating Injuries

Penetrating wounds are most commonly caused by stabbing, gunshot, or shotgun injury.^{40,41} Knife stabbings usually cause superficial lacerations, whereas high-velocity projectiles generally cause injury from capsule to capsule, with massive parenchymal damage.⁵

TABLE 91-1
Classification of Hepatic Trauma

Grade	Injury
I	Hematoma Subcapsular, <10% surface area
II	Laceration Capsular tear, <1 cm parenchymal depth
III	Hematoma Subcapsular, 10%-50% surface area Intraparenchymal, <10 cm diameter
IV	Laceration 1-3 cm parenchymal depth, <10 cm in length
V	Hematoma Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma Intraparenchymal hematoma >10 cm or expanding
VI	Laceration Parenchymal fracture >3 cm deep
V	Laceration Parenchymal disruption involving 25%-75% of hepatic lobe or 1-3 Couinaud segments within a single lobe
V	Laceration Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
VI	Vascular Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular Hepatic avulsion

From Moore EE, Cogbill TH, Jurkovich GS, et al: Organ injury scaling: Spleen and liver (1994 revision). *J Trauma* 38:323-324, 1995.

Iatrogenic Injuries

The liver is subject to a number of iatrogenic misadventures that may be caused by any of the various needles, wires, canulas, and catheters placed by gastroenterologists and interventional radiologists.^{15,42,43} The liver can also be damaged by external cardiac compression during the course of resuscitation and by inappropriately low insertion of a chest tube.⁴⁴

Diagnostic and interventional procedures can produce a tear of the liver capsule, subcapsular hematoma, bile leak, arteriovenous fistula, pseudoaneurysm, arteriohepatic or venobiliary fistula, hepatic hematoma, hemoperitoneum, and biloma.⁴⁵ The prevalence of this problem was well documented in one study in which intrahepatic (77%) and subcapsular (23%) hematomas were found sonographically in 23% of asymptomatic patients evaluated after liver biopsy.⁴⁶

Spontaneous Rupture

Hepatic rupture and hemorrhage can occur in eclamptic or preeclamptic women during the third trimester due to hemolysis, elevated liver enzymes, and low platelets, the HELLP syndrome.⁴⁷ The maternal mortality rate approaches 60% with hepatic rupture. Because surgery is difficult in these friable livers, hepatic artery transcatheter embolization offers a therapeutic alternative. One report showed good results with absorbable gelatin foam (Gelfoam) embolization in four eclamptic patients.^{48,49} Bleeding from the liver may also immediately follow delivery in noneclamptic women.

Spontaneous hemorrhage can occur in patients who have sickle cell anemia, peliosis, hepatomas, hepatic adenoma, coagulopathies, B-cell lymphoma, metastases, organophosphate toxicity, or collagen-vascular disease and in patients who receive long-term hemodialysis.⁵⁰

RADIOLOGIC FINDINGS

Imaging can make a major contribution to the management of trauma patients who are hemodynamically stable and to the postoperative assessment of these patients.*

Computed Tomography of Hepatic Injuries

Multidetector computed tomography (MDCT) is the imaging technique of choice for hepatic trauma and has had an enormous impact on the detection and management of liver injuries.[†] It can reliably diagnose and stage significant hepatic and extrahepatic injuries, document interval healing of hepatic injuries, and diagnose early and delayed complications.⁵⁷ It can also detect associated and unsuspected injuries to other organs (Fig. 91-1). Patients who are hemodynamically unstable require immediate surgery; surgical delay secondary to imaging can be fatal. Hemodynamically stable patients can be scanned in a matter of seconds, with better resolution and with multiplanar imaging capabilities, given our current CT technology.

With any type of abdominal trauma, the first finding that should be evaluated is the presence or absence of blood, either parenchymal or intraperitoneal (hemoperitoneum). Immediately after injury, hematomas on noncontrast scans are hyperdense relative to normal hepatic parenchyma (Fig. 91-2). After

Figure 91-1 Unsuspected hepatic laceration secondary to a gunshot to the left upper abdomen resulting in colonic perforation. CT demonstrates a low-density laceration in the left hepatic lobe (solid arrow). Free air and extravasated rectal contrast material are also seen, indicating bowel perforation (open arrows).

Figure 91-2 Noncontrast appearance of hepatic laceration and hematoma. Noncontrast CT demonstrates a heterogeneous masslike region in the right hepatic lobe with central hyperdensity consistent with hematoma.

intravenous administration of contrast medium, unclotted blood is usually hypodense compared with enhancing normal parenchyma but still usually has an attenuation (20-40 HU) greater than that of simple fluid (0-20 HU).

Active hemorrhage is identified as extravasation of contrast material on contrast-enhanced CT. The attenuation values of extravasated contrast material (155 HU, mean value) and hematoma (54 HU, mean value) help distinguish active bleeding from clotted blood.^{10,58-60} If the liver is involved by focal or diffuse fatty infiltration, a common finding in intoxicated drivers, parenchymal hematomas may appear isodense on contrast-enhanced examinations but can usually be distinguished with narrow CT window settings. In addition, the attenuation and the distribution of fluid can serve as a clue to the site of injury. This phenomenon has been termed the sentinel clot sign.⁶¹ The sentinel clot is the highest density blood collection seen and usually lies adjacent to the injured organ

*References 5, 10, 11, 14, 15, 51-53.

†References 5, 10, 11, 14, 15, 54-56.

(Fig. 91-3). The evaluation of hepatic trauma should also search for other fluid collections, such as bile, as seen in bile leaks and bilomas, which have low attenuation because of their high cholesterol content.

In interpreting CT scans in patients with hepatic trauma, it is important to describe the anatomic site and extent of injury (superficial, deep, lobar, segmental, perihilar), the complexity of the lesion (simple or stellate laceration), and the type of hepatic injury (parenchymal laceration or subcapsular hematoma).^{10,11,62,63}

The major CT findings in blunt hepatic injuries are lacerations, subcapsular and parenchymal hematomas, active hemorrhage, and juxtahepatic venous injuries.¹⁷ Lacerations are the most common injury and appear as branching or linear low-attenuation areas. Lacerations can be classified into superficial (<3 cm from the liver surface) and deep (>3 cm from the surface) (Fig. 91-4). Deep central parenchymal injuries seen on

CT may be unrecognized at laparotomy, especially if the liver surface appears intact, and as a result, the true extent of involvement may be underestimated at surgery.¹⁰ It is imperative to describe any potential laceration extension to the hepatic or portal veins or to the inferior vena cava (Fig. 91-5; see also Fig. 91-3). Hematomas can also occur in hepatic trauma and may be subcapsular or parenchymal in nature. Subcapsular hematomas can be distinguished from free hemoperitoneum by mass effect on the liver surface, creating a contour deformity. Parenchymal hematomas follow the same attenuation values of blood as described before. Again, on contrast-enhanced CT, they may appear relatively lower in attenuation than enhancing liver parenchyma, but their attenuation values are often higher than simple fluid (Fig. 91-6). Yet another type of hepatic injury, contusion, often appears as low-attenuation, sometimes ill-defined areas with intermixed areas of high attenuation representing blood.

Figure 91-3 Patient with blunt abdominal trauma from a motor vehicle accident demonstrates a sentinel clot and free intraperitoneal extravasation of contrast material. **A.** Noncontrast CT image shows a high-density sentinel clot (arrow) adjacent to the spleen (asterisk). **B.** Postcontrast CT image demonstrates a splenic laceration (short arrow) and free extravasation of intravenous contrast material into the peritoneal cavity (long arrow). **C.** Two lacerations adjacent to the right and middle hepatic veins (arrows) are seen extending to the inferior vena cava. The patient was taken to the operating room for hypotensive repair.

Figure 91-4 Patient with a penetrating injury from a stab wound with a 5-inch steak knife while in the shower. **A.** Within the abdominal wall, a hematoma from the stab wound is seen with a blush of contrast material, suggesting active extravasation (short arrow). A liver laceration is also identified (long arrow). **B.** CT image demonstrates the extent of the laceration through the left lobe of the liver (arrow).

Figure 91-5 Grade IV liver laceration and traumatic aortic injury secondary to motor vehicle collision. **A.** CT image demonstrates a central liver laceration involving the middle hepatic vein and extending to the inferior vena cava (arrow). **B.** This image further depicts the degree of injury extending to the portal vein (arrow). **C.** CT of the chest demonstrates mediastinal hematoma and descending thoracic aortic injury (arrow). The patient underwent aortic grafting. Despite this extensive hepatic injury, the patient recovered with nonsurgical management of the liver injuries.

Figure 91-6 Liver laceration with intraparenchymal hematoma. Contrast-enhanced CT demonstrates a low-density hepatic laceration in the right lobe of the liver with a centrally located high-density collection consistent with an intraparenchymal hematoma (arrow).

Active extravasation on contrast-enhanced CT represents one of the more severe CT features of hepatic injury and can herald life-threatening, active bleeding (Figs. 91-7 and 91-8). On CT, this appears as very high attenuation approximating that of aorta (91–274 HU; mean, 155 HU) compared with the density of clotted blood (28–82 HU; mean, 54 HU).⁶⁰ At times, active extravasation of contrast material may be difficult to distinguish from a pseudoaneurysm. Delayed contrast images are helpful in this instance, demonstrating “washout of contrast attenuation” with pseudoaneurysms (approximating the blood

pool density at that time) and persistence of high density with active bleeding.⁶⁴ Active extravasation of contrast material has been shown to be a strong predictor of potential cardiovascular collapse and failure of nonsurgical management.^{65,66} Treatment of active extravasation is best performed through angiographic embolization.⁶⁷

Vascular injuries of the liver, although relatively rare, can be fatal as well. When these occur, they are usually due to lacerations extending to the inferior vena cava, hepatic veins, and portal veins; thus, it is imperative to identify and to relay this extension to the clinicians (see Fig. 91-3). Alternatively, avulsion of the vessels can occur as well. Inferior vena cava injuries carry a particularly high mortality rate and should be suspected when there is a laceration extending to the proximal hepatic veins and inferior vena cava and when there is a large amount of retrohepatic blood.⁶⁸ If bleeding occurs at the bare area of the liver, there may be extension of blood into the retroperitoneum as well.

Periportal zones of decreased density may be the only manifestation of hepatic trauma. These may represent linear collections of blood in the periportal regions or dilated periportal lymphatics.^{69–71} Periportal low density was previously thought to be an important sign of liver injury but is actually most commonly due to rapid fluid resuscitation, elevating central venous pressure, as suggested by a distended inferior vena cava (Fig. 91-9).^{69–72} Periportal low density may also be seen in nontraumatic causes, including in patients with congestive heart failure, patients with hepatitis, liver transplant recipients, and those with AIDS. The lucency is due to a dilation of the intrahepatic lymphatics caused by obstruction of drainage. Intraparenchymal gas, in the absence of infection, has also been reported in patients with blunt abdominal trauma, but an abscess must always be excluded when extraluminal gas collections are present.^{73,74}

Figure 91-7 Hepatic laceration with active extravasation. **A.** CT shows a low-density laceration in the posterior segment of the right hepatic lobe. Focal hyperdensity consistent with active extravasation of contrast material and active hemorrhage is seen (arrow). **B.** A coronal reformatted image further reveals the extent of active extravasation (arrow). High-density fluid in the peritoneal cavity is consistent with hemoperitoneum.

Figure 91-8 Liver contusion and laceration with active bleeding. **A.** CT image shows an ill-defined hepatic contusion in the right lobe of the liver (arrowhead) in contrast with the lower density, well-defined laceration in the left lobe of the liver (arrow). **B.** CT image reveals active extravasation of contrast material, connoting active bleeding in the laceration track (long arrow). Hepatic contusion is demonstrated again (short arrow). **C.** A more inferior CT image shows the laceration to completely transect the right lobe of the liver (arrow). The injury involves the right kidney as well with a renal laceration and perinephric hematoma (arrowhead).

A CT-based classification has been formulated from these findings (Table 91-2). This CT classification system grades the injuries; however, this grading system and the CT features may not correlate with the need for surgery.^{75,76} It is not the grade of the injury but rather the hemodynamic parameters of the patient that often dictate conservative versus operative management decisions.²² Even major hepatic injuries up to and including grade IV can usually be managed conservatively if the patient is hemodynamically stable.^{28-31,63,75} CT findings associated with increased morbidity, mortality, and need for operation include deep perihilar lacerations, failure of the hemoperitoneum to be significantly resorbed within 1 week,

rapid progression of hepatic injuries within hours or days of injury, and major vascular trauma (especially injury to the confluence of hepatic veins).^{13,77} It has been noted that many hemodynamically stable patients can avoid operation despite significant injuries seen on CT examination. Although the CT-based injury grading system may not correlate with the need for surgery, it serves as a consistent means of describing and communicating injuries to surgeons. Radiologists should therefore be familiar with this grading system.

The need for follow-up CT examination to detect delayed complications is favored by some⁷⁸⁻⁸⁰ and opposed by others.^{28,81,82} Patients with persistent or worsening symptoms should have

Figure 91-9 Periportal edema secondary to aggressive hydration in a patient with a stab wound. Periportal lucency extending along both sides of the intrahepatic portal veins indicates periportal edema. This is a nonspecific finding that is most commonly seen with rapid intravenous hydration.

TABLE 91-2 CT-Based Classification of Blunt Hepatic Trauma	
Grade	Criteria
1	Capsular avulsion, superficial laceration(s) <1 cm deep, subcapsular hematoma <1 cm maximal thickness, periportal blood tracking only
2	Laceration(s) 1-3 cm deep, central/subcapsular hematoma(s) 1-3 cm diameter
3	Laceration(s) >3 cm deep, central/subcapsular hematoma(s) >3 cm diameter
4	Massive central/subcapsular hematoma >10 cm, lobar tissue destruction (maceration) or devascularization
5	Bilobar tissue destruction (maceration) or devascularization

follow-up examinations.⁸¹ Patients with more severe, complex hepatic injuries may also benefit from repeated CT to evaluate injury status and possible complications.^{9,21,83,84} Meredith and colleagues²⁸ found that hemodynamic stability and lack of peritoneal findings were more predictive than the CT findings of which patients could undergo nonoperative management.

Post-traumatic complications are not uncommon after hepatic injury and are best demonstrated by CT as well.^{78,79} Delayed hemorrhage can occur and can have a high mortality rate. This may be due to several causes, including an expanding injury, a biloma-induced pseudoaneurysm, a misinterpretation of contrast material extravasation on the initial CT scan, and mismanagement of the patient's hemodynamic status (Fig. 91-10).⁸³ This should be suspected if there is a delayed drop in the hematocrit level. Post-traumatic pseudoaneurysms of the hepatic artery and its branches may occur weeks to months after the initial injury. These patients present with delayed hemorrhage and hemobilia (if the pseudoaneurysm decompresses into the biliary system) and should be evaluated with hepatic angiography, at which time the aneurysm can be embolized to

minimize the risk of frank rupture.⁸⁵⁻⁹¹ Bilomas (Fig. 91-11) and intrahepatic and perihepatic abscesses are other major post-traumatic complications. Bilomas are seen in 0.5% to 20% of patients managed nonoperatively.^{8,29,53,92} These fluid collections usually resolve or can be managed successfully by percutaneous drainage.⁹² Aspiration, biliary scintigraphy, or magnetic resonance imaging (MRI) may be necessary for differentiation of these fluid collections.^{35,85} Endoscopic retrograde cholangiopancreatography (ERCP) can identify the bile leak and guide the insertion of a biliary endoprosthesis.

Ultrasound

Ultrasound is being more frequently performed in the emergency department by surgeons, radiologists, and emergency department physicians. The advantages of sonography include portability, ability to rapidly detect intraperitoneal blood, and relative inexpense. Problems include the operator-dependent nature of ultrasound and limitations in demonstrating the extent of injury.

The use of ultrasound was pioneered years ago in the European literature.⁹³ Ultrasound can be used either to identify parenchymal injury directly or to detect intraperitoneal fluid that in the acute setting is presumed to represent hemoperitoneum.^{94,95} Ultrasound is much more accurate in the detection of hemoperitoneum than in the diagnosis of specific parenchymal or hollow viscus injury. The recent interest in ultrasound is primarily in its utility as a rapid screening test for significant injury, the so-called focused abdominal sonogram for trauma (FAST).^{96,97} FAST simply entails sonographic interrogation of sites in which free intraperitoneal fluid most often accumulates: Morison's pouch, the left subphrenic and subsplenic areas, and the pouch of Douglas. It also involves evaluation for the presence of hemopericardium. According to Ma and coworkers,⁹⁸ the suprapubic view is the single view most sensitive for hemoperitoneum (68%), but the sensitivity dramatically increases when multiple views are obtained. The best use of FAST is to triage patients. A hemodynamically stable patient with an abnormal finding on FAST should undergo CT scanning, whereas an unstable patient with an abnormal ultrasound finding should go to surgery emergently. Clinical management in cases with a normal finding on FAST is more nebulous, but at a minimum, those patients should at least be observed for a time.

Multiple studies have been published looking at the accuracy of ultrasound and comparing it with other modalities. In general, ultrasound is relatively sensitive for the detection of free intraperitoneal fluid, but it is far from perfect. There are a wide range of values in the literature for sensitivity (81%-94%), specificity (88%-100%), and accuracy (86%-98%) for free intraperitoneal fluid.⁹⁹⁻¹⁰⁹ This type of variability suggests inconsistent reproducibility of the method. In addition, for these values to be attained, some studies required repetitive sonographic scanning to detect developing fluid. Another confounding factor is that not all blunt abdominal trauma causes free fluid, with false-negative results. In some studies, 26% to 34% of patients with abdominal organ injuries did not have hemoperitoneum.¹⁰⁹⁻¹¹¹ Therefore, although ultrasound is very good in detecting hemoperitoneum, there are false-negative and false-positive findings. Diagnostic peritoneal lavage is a method to detect hemoperitoneum that was used commonly before the advent of ultrasound and CT. Diagnostic peritoneal lavage is known to be more sensitive than ultrasound in the detection of

Figure 91-11 Bilomas. **A.** Biloma (B) after a gunshot wound to the liver. The large low-attenuation (5 HU) collection in the liver was aspirated and proved to be a biloma. **B.** Different patient who is status post gunshot wound with a large liver laceration (arrow) that extends posteriorly to involve the right adrenal gland. **C.** CT performed a few days later shows a collection in the right lobe of the liver (arrow). Contusion is also seen (arrowhead). **D.** A drain was placed by interventional radiology and contrast material administered through the tube, demonstrating communication with the biliary tract (arrow) consistent with a biliary injury and biloma.

fluid and injury; however, positive diagnostic peritoneal lavage results led to a 30% rate of nontherapeutic, unnecessary laparotomies.^{23,24} Diagnostic peritoneal lavage has been largely replaced with ultrasound and CT. In addition to the evaluation for hemoperitoneum, ultrasound can be used to detect other injuries. Ultrasound can demonstrate a number of traumatic lesions: subcapsular hematomas, parenchymal tears, contusions, and bilomas. A subcapsular hematoma appears as a lentiform or curvilinear fluid collection with echogenic properties that vary with the age of the lesion (Fig. 91-12). Hematomas are initially anechoic, but as clotting proceeds, they become progressively echogenic by 24 hours. As time passes, the hematoma's echogenicity begins to decrease again.^{112,113} Internal echoes and septations develop within these collections in 1 to 4 weeks. The frequency of the transducer also determines the sonographic characteristics of the hematoma. The complexity and echogenicity of the hematoma can appear greater at higher frequencies as a result of higher spatial resolution.^{5,112-114}

Parenchymal contusions are normally hypoechoic at initial presentation, transiently become hyperechoic, and then become hypoechoic. Lesions that occur posteriorly in the right lobe or over the spine within the left lobe are usually not sonographically demonstrable unless the patient has a slender body habitus.⁸⁹ Parenchymal tears, with or without hematoma, are manifested as irregular defects with abnormal echotexture relative to the surrounding normal tissue. Intraparenchymal hematomas as small as 3.5 mL can be visualized as rounded, echogenic foci.¹¹⁵

Bilomas appear as rounded or ellipsoid, anechoic, loculated structures with sharply defined margins close to the liver and bile ducts.¹¹⁶⁻¹¹⁸ Scintigraphy is an important adjunct in these

cases to show communication of the lesions with the normal biliary tract. Fluid aspiration may be helpful to demonstrate bile.^{119,120} Ultrasound is particularly helpful diagnostically when the collections no longer communicate with the biliary tract. Percutaneous drainage with CT or sonographic guidance may be helpful when fluid collections are symptomatic or infected.

Many studies have evaluated the accuracy of ultrasound for detection of parenchymal hepatic and other solid organ injuries. Sensitivity for detection of all injuries ranges from 43.6% to 93%. This wide range of numbers is due to many factors, including study design, technique, and experience. Papers with very low sensitivities often include small bowel and mesenteric injuries, which are extremely difficult to detect by ultrasound. With respect to liver parenchymal injury specifically, an article by Sato and Yoshii⁹⁹ comparing ultrasound examination with both the clinical outcome and CT revealed a sensitivity for hepatic injury of 87.5% among experts and 46.2% among non-expert sonographers. This suggests that detection of injuries sonographically is more difficult than simply scanning for hemoperitoneum and can be variable. Other pitfalls of ultrasound, however, include limitations in the evaluation of retroperitoneal injuries, diaphragmatic injuries, and hollow viscus perforations.

Some authors have experimented with contrast-enhanced ultrasound in the evaluation of hepatic trauma. These contrast agents use stabilized, encapsulated microbubbles that are small enough to pass through the pulmonary circulation to reach the systemic circulation and ultimately parenchymal tissue. Contrast agents have many potential uses in the heart and vascular system as well as in the detection of focal lesions. In the trauma setting, Catalano and associates¹²¹ have demonstrated that

Figure 91-12 Subcapsular hematoma on ultrasound in a pregnant patient with HELLP syndrome. **A.** Extensive subcapsular hematoma is subtly delineated adjacent to the left lobe of the liver on this longitudinal ultrasound scan (arrowheads). **B.** Subcapsular hematoma is also seen adjacent to the right lobe of the liver (arrowhead). **C.** Noncontrast CT shows the corresponding CT appearance of sentinel clot in the subcapsular hematoma (asterisk). **D.** Contrast-enhanced CT also shows the subcapsular hematoma (asterisk).

contrast-enhanced sonography is a promising tool that better depicts hepatic lacerations and hematomas as echo-poor areas against a background of enhanced parenchyma. It also appears to demonstrate the extent of lesions better than conventional sonography.¹²² In addition, it may also have a role in detecting active extravasation of contrast material and therefore active bleeding, which cannot be done with conventional ultrasound. In their study, contrast-enhanced sonography had a higher sensitivity for hepatic injury detection compared with routine ultrasound, 87% versus 65%.¹²¹ This may potentially be a powerful tool in the emergency department setting in the future.

Nuclear Scintigraphy

Bile leaks are rare in blunt hepatic trauma. They more often follow cholecystectomy and partial hepatectomy. Hepatobiliary scans, the most sensitive means of detecting bile leakage, may identify the leak before the onset of clinical symptoms.¹²³ With bile leakage, the tracer may appear as a subcapsular collection or may pool freely in the peritoneal cavity. Parenchymal injuries such as lacerations and hematomas are easily identified on early hepatic phase images.¹²⁰

Magnetic Resonance Imaging

Gadolinium-enhanced MRI can depict complex hepatic injuries in patients with contraindications to iodinated contrast material.¹²⁴ Contrast-enhanced MRI has been shown to demonstrate traumatic hepatic injuries equal to and, occasionally, better than contrast-enhanced CT.¹²⁴ MRI, however, requires a longer imaging time as well as the need to accommodate metallic life support and monitoring equipment, which is more difficult than with CT. In addition, the MR screening process, which is necessary for the safety of the patient, is a timely process that is often not possible in a trauma setting where immediate decisions need to be made. Furthermore, images are compromised by motion to a greater extent than with CT as well as by limited evaluation of the bowel. MRI can help differentiate bilomas from subacute hematomas.¹¹ Despite these limitations, MRI may have a role in imaging of the trauma patient, although its use has not been thoroughly evaluated.¹²⁵ With the advent of gadolinium-based hepatobiliary agents such as gadobenate dimeglumine (MultiHance; Bracco Diagnostics) and gadoxetate (Eovist; Bayer HealthCare), the biliary tree can be evaluated in a functional way.¹²⁶ These hepatobiliary agents have dual excretion through the kidneys and liver. The contrast

agent is taken up by the hepatocytes and excreted through the biliary tree. Approximately 50% of gadoxetate is excreted through the liver, whereas 5% of gadobenate has hepatobiliary excretion. This biliary excretion allows visualization of the bile ducts and any bile leaks or bilomas on T1-weighted MR sequences, on which the gadolinium portion of these agents will cause T1-weighted shortening and increased signal on T1-weighted images. Imaging for the hepatobiliary phase of biliary excretion is done in a delayed fashion after routine images. With Eovist, a delay of approximately 20 to 30 minutes is used; with MultiHance, a delay of 60 minutes is optimal. The few studies performed for the evaluation of bile duct injury have been in iatrogenic injuries after surgery. In this setting, MR has been shown to find and to characterize bilomas with a sensitivity of 80% to 96%.^{127,128} Many other types of biliary abnormalities, including strictures, leaks, obstructions, and anatomic anomalies, can be depicted with these agents (Fig. 91-13). Although it is still a Food and Drug Administration off-label application of these agents, functional biliary imaging with these contrast agents is extremely promising. Apart from identifying biliary injury, MRI may also have a role in follow-up of previously detected hepatic injuries. In severe hepatic injury in which follow-up imaging is warranted, the use of MRI over CT may save a significant radiation dose to often young patients, particularly if multiple follow-up examinations may be needed.

Angiography

Once the mainstay of hepatic trauma diagnosis, angiography is now usually performed to investigate and to treat severe and active hemorrhage, post-traumatic fistulas, and pseudoaneurysms.⁸⁶ Angiography, however, plays a pivotal role in the conservative management of hepatic injury. One of angiography's main roles is to treat active bleeding, which appears as extravasation of contrast material on CT.¹²⁹ In this capacity, angioembolization has a reported efficacy of 83% in controlling bleeding after blunt hepatic injury according to Carrillo and associates.¹³⁰ Numerous other studies have shown even greater success of angioembolization in the control of bleeding, minimizing transfusions and need for surgery.¹³¹⁻¹³⁴ Traumatic pseudoaneurysms, arteriobiliary fistulas, arteriovenous fistulas, and portobiliary fistulas are the major sources of occult or delayed hemorrhage in the traumatized liver. These vascular abnormalities are amenable to transarterial embolization with either

Figure 91-13 Use of MRI in demonstrating biliary leak with Eovist contrast agent. **A.** Axial T1-weighted fat-saturated MR image in the delayed hepatobiliary phase of enhancement reveals excretion of contrast material in the bile duct (arrowhead). A second area of excretion is seen in the gallbladder fossa, which is nonanatomic (arrow). **B.** Coronal T1-weighted fat-saturated image from the same examination shows the biliary excretion into the common bile duct (arrowhead) and the other area of excretion (arrow) that represents a biliary leak.

Gianturco coils or detachable balloons. Gelfoam and Ivalon usually produce only transient hemostasis in patients who have had multiple blood transfusions.^{14,86-92} Transcatheter arterial embolization has been demonstrated to be an effective alternative to surgery in patients with high-grade (Mirvis classification 3 or 4) injuries to the liver and, in one series, was successful in all patients.⁹² Interventional radiologists can manage some of the most lethal venous injuries, including lacerations of the inferior vena cava, with stenting.¹³⁵

Plain Radiographs

Plain radiographic findings are neither sensitive nor specific in patients with hepatic trauma. Nearly 50% of patients with hepatic trauma have fractures of the right lower ribs. When hemoperitoneum is present, there may be loss of the inferior liver-fat interface. Hepatomegaly, irregularity of the liver margin, and caudal displacement of the hepatic flexure all suggest liver injury. Pulmonary contusion, pneumothorax, elevation of the right hemidiaphragm, pleural effusion, hemothorax, and diaphragmatic irregularity frequently accompany hepatic trauma as well.^{4,14,89,136,137}

TREATMENT

Management of blunt abdominal trauma has undergone a complete paradigm shift in the past two decades.^{138,139} Whereas 80% to 90% of injuries were treated operatively in the 1990s, the majority of patients with blunt hepatic trauma and penetrating liver injuries are now managed nonoperatively if they are hemodynamically stable.^{7-9,27,28} As previously stated, it is not the grade of the liver injury but rather the hemodynamic parameters of the patient that determine operative versus conservative management.⁸⁴ Validation of conservative management has been substantiated by lower acute mortality rates and acceptable short-term morbidity and complications relative to exploratory surgery and emergent hepatic resections.^{12,140-142} In patients with American Association for the Surgery of Trauma grade I to grade III liver injuries, the need for surgical exploration after initial resuscitation and observation is usually less than 10% to 20%.^{12,140,141} If patients with grade IV to grade VI injuries can be nonoperatively stabilized, a period of resuscitation and CT imaging may improve the ultimate outcome of emergent surgery by preoperatively defining the extent and location of specific hepatic injuries. Any nonoperative management, however, requires capabilities for close monitoring and operating room availability for potential urgent intervention. Also, adjunctive therapies including embolization by interventional radiology, percutaneous drainage, endoscopy, ERCP, and laparoscopy need to be readily available.¹³⁴

In patients with severe trauma in whom there is massive bleeding, large amounts of devitalized tissue, or massive bile leak and in the clinical scenario of rebleeding, persistent decline of hemoglobin, or failure of embolization, operative intervention is considered.¹⁴³ First, treatment of shock and of head and thoracic injuries has priority; next, abdominal injuries should be addressed.¹⁴⁴ For severe liver injury (grade IV or V), three main surgical principles are control of hemorrhage, drainage of infection, and repair of the biliary system. Bleeding is controlled by specific ligation or direct control of bleeding points; débridement and ligation; hepatic artery ligation; more extensive hepatic resection; tamponade with perihepatic packing; and in

extreme cases of venous avulsion, vena cava occlusion, with or without shunting, or cava resection with graft replacement. Injuries to the hepatic veins are the major cause of immediate death from hepatic trauma and are difficult to repair. In patients who decompensate during surgery, damage control surgery can be done; this consists of perihepatic packing and partial closure of the abdominal incision to allow the patient to go to the intensive care unit for resuscitation and correction of any metabolic derangements and then to return to the operating room when the condition is more stable.²² In patients with extreme uncontrolled bleeding, liver transplantation has been performed in rare cases. Patients with a cerebral intraparenchymal bleed demonstrated on head CT scans are difficult to manage because they may be harmed by the effects of general anesthesia and the fluid shifts that accompany laparotomy, evacuation of hemoperitoneum, and repair of the liver injury.⁷⁷ Operative hemostasis and adequate débridement may be difficult, and hepatic surgery carries the risk of postoperative sepsis.⁷⁹ After operative control of hemorrhage, the liver is drained externally. Finally, biliary injury must be recognized and repaired as it will not heal spontaneously.¹⁴⁵ In patients with penetrating injury, nonoperative management is attempted for stab wounds and low-velocity gunshot wounds in stable patients in the absence of other injuries. If the patient is unstable or has associated bowel injury, surgery is then mandated.²²

COMPLICATIONS

Although the need for surgery is not dependent on the CT grade of injury, the grade of injury and CT findings can prognosticate the chance for the development of complications. Patients with higher grade injuries (grades III-V) are more likely to experience complications. According to Kozar and coworkers, 21% of patients with a grade IV injury and 63% of patients with a grade V injury developed hepatic complications.^{30,138,146} Therefore, with high-grade injuries that undergo nonoperative management, complications should be anticipated, and access to means of treating and monitoring these complications should be readily available.

Bleeding

Bleeding is the most common complication that occurs after trauma.^{29,143} The majority of the time, this can be managed successfully with angioembolization, but rarely surgery is required. Most episodes of bleeding occur early, either on the day of the injury or shortly thereafter. There can be cases of delayed hemorrhage that are due to either delayed rupture of a hematoma or pseudoaneurysm formation. Angioembolization is a vital tool in the management of bleeding at any time during treatment.

Infection

Sepsis and hepatic abscess are serious complications that are far more common with operative than with nonoperative management. Hematomas and bilomas are excellent media for the development of infection. In traumatized patients, bacteria may enter the body through intravenous sites, various indwelling catheters, surgical drains, and other injured areas and by translocation from the gastrointestinal tract.^{63,80} In patients with a suspected intra-abdominal source of sepsis, all intrahepatic or perihepatic fluid collections seen on imaging studies should be viewed with suspicion as a source of infection.⁶³

Biliary Tract Complications

Intrahepatic or extrahepatic biliary tract complications, including biliary leaks, biloma, and bile peritonitis, are being detected with increasing frequency in patients with hepatic trauma because of the increased sensitivity of cross-sectional imaging and hepatobiliary scintigraphy.^{35,63,112,116,118} These lesions may take days to weeks to become manifested clinically owing to the slow rate of leakage from the injured bile duct. Most bilomas are asymptomatic and detected by imaging. CT scans and sonography demonstrate nonspecific fluid collections. Most often, bilomas and bile duct injury can be adequately treated by percutaneous drainage or ERCP stenting, but in rare cases, surgery may be needed.¹³⁸

Hepatic Surgery

Hepatic surgery has been likened to an exercise in hemostasis.^{147,148} No bloodless planes exist, as the liver's complex inflow

and outflow tracts course at right angles. The liver parenchyma is also friable and soft and has few landmarks.¹⁴⁹ These factors had hindered the evolution of hepatic surgery to such a degree that before the 1950s, segmental hepatectomy was reserved almost exclusively for trauma.¹⁴⁹ With advances in surgical techniques and anesthesia and a better understanding of internal vascular anatomy (Fig. 91-14) and hepatic physiology, partial hepatectomy has become a safe and accepted mode of therapy for selected patients with primary and metastatic liver tumors as well as certain benign disorders (Table 91-3).¹⁵⁰⁻¹⁵⁴

Two major principles are fundamental to planning of hepatic resection.¹⁵⁵⁻¹⁵⁸ First, there must be a sufficient amount of hepatic parenchyma to sustain life after surgery. The liver possesses a remarkable capacity to regenerate itself; up to 80% can be safely removed in many patients. Regeneration of liver volume is an efficient, progressive process that in animal studies requires approximately 4 months after an 80% to 85% resection.^{155,157} Coexisting hepatocellular diseases such as cirrhosis decrease the amount of hepatic reserve so much that some

Figure 91-14 Segmental hepatic anatomy: Couinaud's nomenclature. This classification is vital to an understanding of the surgical vascular anatomy of the liver. **A.** Except for the falciform ligament, the liver has few topographic landmarks. Segment I, caudate lobe (not shown); II and III, lateral segment of the left lobe; IV, medial segment of the left lobe; V and VIII, anterior segment of the right lobe; VI and VII, posterior segment of the right lobe. **B.** Schematic representation of the segments. The three main hepatic veins lie within scissurae and divide the liver into four sections. The caudate lobe (I) is its own autonomous lobe in the French system. **C.** The segmental anatomy of **A** is depicted to show the scissurae and the caudate lobe. (**A** from Sabiston DC Jr [ed]: *Textbook of Surgery*, 13th ed. Philadelphia, WB Saunders, 1986. **B** and **C** from Bismuth H: *Surgical anatomy*. In Blumgart LH [ed]: *Surgery of the Liver and Biliary Tract*. Edinburgh, Churchill Livingstone, 1988, pp 1–37.)

TABLE 91-3 Indications for Hepatic Resection

Indication	Frequency (%)
Metastatic tumor	60
Primary malignant neoplasm	15
Undiagnosed mass	8
Benign tumor or cyst	7
Trauma	5
Localized biliary abnormality	3

patients are unable to tolerate removal of any tissue. Indeed, total hepatectomy and liver transplantation may be the best way to treat patients with small hepatomas or severe cirrhosis.¹⁵⁹⁻¹⁶¹

The second major principle of hepatic resection is preservation of blood supply to the liver tissue left in situ. Adherence to this principle is difficult because the vascular supply is not apparent to the surgeon on inspection of the hepatic surface. In addition, hepatic veins and arteries do not lie in parallel courses, as they generally do in other organs.

RADIOLOGY IN SURGICAL PLANNING

Imaging studies play an important role in identifying the extent of disease that is important for prognosis and therapy. For example, the number and size of hepatic metastases from colorectal neoplasms and extrahepatic involvement determine long-term survival in patients with hepatic resection.¹⁶²⁻¹⁶⁴ The radiologist can help the surgeon adhere to these principles by providing the following information before hepatic resection^{155,157,164-167}:

- Anatomic location of the lesion in relationship to the portal and hepatic veins, fissures, coronary and falciform ligaments, and fissure for the ligamentum venosum
- Presence of vascular invasion of the hepatic vessels by a neoplasm
- Bland or tumor thrombus in portal and hepatic veins distant from the lesion of interest
- Involvement and patency of the inferior vena cava
- Spread of tumor into adjacent structures (e.g., diaphragm, colon, duodenum, lymph nodes)
- Confirmation to the maximal extent possible that the lobe of liver to remain in situ is free of tumor

Preoperative studies should include a chest radiograph and chest CT scan to exclude extrahepatic metastases. MDCT or MRI of the liver and the remainder of the abdomen should also be obtained. Removal of multiple liver metastases is possible in some patients.

A common anomaly, the replaced right hepatic artery arising from the superior mesenteric artery, is important for the surgeon to appreciate preoperatively. Other vascular and biliary variations should be noted as well. The placement of a hepatic artery infusion catheter for chemotherapy may require CT arterial portography to better demonstrate the arterial anatomy and lesions; however, the quality of CT and MRI has improved to such a degree that CT arterial portography is less commonly performed. Because aberrant vessels may course laterally and

more posteriorly in the porta hepatis, dissection of the porta hepatis may be modified if an anatomic anomaly is noted preoperatively.¹⁶⁸

INTRAOPERATIVE ULTRASOUND

Intraoperative ultrasound of the liver can function as both a diagnostic and a therapeutic tool. As a diagnostic aid, intraoperative ultrasound has proved successful for the following indications: to detect small (1-5 cm), nonpalpable, parenchymal liver lesions not detected by preoperative imaging studies; to precisely define the topography of liver tumors and their relationship to the vessels, allowing segmental resections to be performed; to guide intraoperative biopsy or ablative treatments of impalpable lesions; and to differentiate liver neoplasms from certain benign lesions, such as cysts and hemangiomas¹⁶⁹⁻¹⁷⁵ (Figs. 91-15 and 91-16). Several studies have documented the utility of this technique, particularly with its initial use. In the study of Conlon and coworkers,¹⁷⁶ the information provided by intraoperative ultrasound changed the preoperative surgical plan in 18% of patients and provided additional useful information not available preoperatively in 47%, including detection of subcentimeter lesions, lesion characterization, and anatomy of hepatic vasculature. In another study, the sensitivity of intraoperative ultrasound for lesion depiction was 94.3% compared with 86.7% for MRI. However, in this study, in only 4% of the patients did intraoperative ultrasound alter surgical management secondary to additional lesion detection.¹⁷⁷ Another study demonstrated intraoperative ultrasound to change surgical management in only 7% of patients.¹⁷⁸ Wagnetz and colleagues¹⁷⁹ compared intraoperative ultrasound with 1.5T MRI and 64-MDCT and found that the sensitivity of ultrasound for lesion detection was 95.1% compared with 96.8% for MDCT and 94.4% for MRI. Furthermore, MDCT and MRI had a slightly higher negative predictive value than intraoperative ultrasound for identifying disease-free segments in the liver. In only 2.7% of cases was management changed after intraoperative ultrasound. An article by Mui and associates evaluating intraoperative sonography in detection of liver metastases in pancreatic adenocarcinoma found that ultrasound changed management in only 1% of cases. In comparison to initial studies, these more recent studies demonstrate a decreased percentage of cases in which intraoperative ultrasound alters surgical management. This is thought to be partly attributed to technologic advances in preoperative studies such as MRI, resulting in improved selection of patients.¹⁷⁸

Recent interest has arisen in the use of intraoperative contrast-enhanced ultrasound for liver lesion detection, citing increased lesion detection rates relative to noncontrast ultrasound and CT.^{180,181} Despite somewhat conflicting data, intraoperative ultrasound continues to be an important component of hepatic resection for purposes of lesion localization and relationship to hepatic vasculature and biliary structures, segmental localization, and further evaluation for incompletely characterized subcentimeter lesions identified on preoperative imaging studies. Intraoperative ultrasound also helps detect occult extension of hepatic tumors into vascular structures and assists in intraoperative biopsy of liver lesions.¹⁷⁷ Intraoperative ultrasound has also proved useful in guiding intraoperative cryotherapy and radiofrequency ablation in the treatment of liver tumors.¹⁸²⁻¹⁸⁴

Figure 91-15 Utility of intraoperative ultrasound in a patient with rectal cancer and concern for a liver metastasis. **A.** Axial postcontrast CT image reveals a small low-attenuation lesion (arrow) that was new from the prior CT examination and interpreted as suspicious for metastasis, given its interval development. **B** and **C.** Intraoperative ultrasound reveals the questioned lesion on CT to represent a cyst (arrows).

Figure 91-16 Use of intraoperative ultrasound in detecting more lesions in a 36-year-old woman with a hepatic lesion thought to represent an adenoma but with symptoms of pain. **A.** Intraoperative ultrasound reveals the large hypoechoic mass (arrow). **B.** An echogenic lesion characteristic of a hemangioma was also seen (arrow). **C.** An additional unsuspected small hypoechoic mass was also identified (arrow). The dominant lesion is again seen (arrowhead). The hypoechoic lesions were resected and found to represent hepatic adenomas removed because of the patient's symptoms.

INDICATIONS

As surgical techniques become safer, the indications for hepatic surgery are broadening (see Table 91-3).

Benign Lesions

The indications for resection of a benign tumor or cyst include risk of rupture or hemorrhage, symptoms, risk of malignant transformation, and enlargement of the mass so that it is causing pressure on bile ducts, the liver capsule, or adjacent organs. Fenestration-resection is rarely required for cosmetic or symptomatic improvement in patients with adult polycystic liver disease.^{185,186}

Localized biliary abnormalities, such as hepatolithiasis and segmental Caroli's disease, are other indications for resection. Hepatic abscesses that do not respond to medication or percutaneous drainage may also require surgical resection.

Malignant Lesions

Resection of liver metastases is the most common indication for partial hepatectomy in the United States. Liver metastases are an enormous clinical problem in view of the fact that approximately 25% of all malignant neoplasms eventually spread to the liver (Table 91-4). It is the most common site of blood-borne metastasis and more often than not is a major contributor to the patient's demise.¹⁸⁷ Neoplasms grow five to seven times faster in the liver than in most other organs.¹⁶⁶ This is precisely why untreated liver metastases augur such poor survival. Colorectal metastasis is the most commonly resected hepatic tumor in the United States. Five-year survival rates of 25% to 40% for solitary metastases confined to one lobe have been reported.^{178,182-184} In a recent meta-analysis, the overall median survival for all colorectal metastases resected was 3.6 years.¹⁸⁸ Hepatoma is the most commonly resected tumor worldwide owing to its prevalence in portions of the Far East and Africa. Technical improvements in hepatic resection and earlier diagnosis have increased the resectability rates. Patient selection is paramount in the success of hepatic resection for hepatocellular carcinoma. In fact, according to the Barcelona Clinic Liver Cancer group staging system, which has been integrated into the American Association for the Study of the Liver guidelines, hepatic resection has a marginal role in the treatment of hepatocellular carcinoma and is indicated in patients with early-stage hepatocellular carcinoma.¹⁸⁹ Early-stage hepatoma is defined by the Milan criteria,¹⁹⁰ normal clinical performance status, and preserved liver function. Liver resection in such

patients (as well as higher stage) yields favorable 3- and 5-year survival rates of 78% and 39%.^{191,192}

Hepatic Resection for Liver Metastases

With the knowledge that patients with limited metastatic disease may benefit from liver resection, there has been a marked increase in the number of hepatic resections performed during the 1980s and 1990s.

Advances in the techniques of liver resection and extensive preoperative evaluation with careful patient selection have reduced operative mortality rates to less than 5%.¹⁹³⁻²⁰² This improvement in operative morbidity and mortality is attributed to several different factors. Our improved understanding of the segmental anatomy of the liver and specifically of its intrahepatic blood supply has made for safer hepatic resections with minimized blood loss. In addition, improved preoperative diagnostic imaging has excluded patients from operation in whom the operative risks due to major vascular involvement would have resulted in major complications. Resection techniques including vascular inflow occlusion, minimized parenchymal destruction, decreased intraoperative blood loss, and successful management of postoperative complications have improved the safety of this operation. As a result, the operative morbidity and mortality associated with hepatic surgery have significantly decreased, with most current studies reporting operative mortality rates between 2% and 7%.¹⁹³⁻²⁰²

Improved long-term results after hepatic resection are due not only to decreased perioperative mortality and morbidity but also to an improved understanding of the biology of liver metastases and thus the selection criteria for surgery.

Selection of Patients for Resection

If we accept that certain patients with limited hepatic disease will benefit from surgical resection, then careful analysis of the survivors will allow us to identify specific prognostic factors useful in selecting appropriate patients for resection. Much of our knowledge regarding prognostic variables affecting patient outcome after hepatic resection is derived from the collected data of the registry of hepatic metastases by Hughes and associates.¹⁹⁸ This retrospective series analyzed 862 patients from multiple institutions who had undergone hepatic resection for metastatic colorectal cancer. In addition to data from the registry of hepatic metastases, other single-institution reviews have helped identify prognostic features related to the patient, primary tumor characteristics, and features of the liver metastases.

Patient characteristics not thought to influence survival include gender and age of the patient. Currently, a patient's physiologic performance status rather than chronologic age or gender is the major determinant excluding the patient from consideration for resection. Patients with poor hepatic function due to advanced cirrhosis are also considered poor candidates for liver resection.²⁰²

A number of prognostic factors related to the tumor can affect survival of the patient.¹⁸⁸ The *stage and histologic grade of the primary tumor* are thought to be important prognostic factors. In the Hughes registry, patients presenting with regional lymph node metastases (stage III) had a 5-year survival rate of 23% compared with 47% for patients without regional lymph node involvement (stage II).¹⁹⁸ In addition, other retrospective studies have suggested that patients with poorly differentiated, high-grade primary tumors have a shorter survival benefit after

From Foster JH: *Surgical treatment of metastatic liver tumors. Hepatogastroenterology* 37:182-187, 1990.

resection of liver metastases.²⁰³ Finally, patients with primary tumors originating in the rectum may derive less benefit from resection of hepatic metastases. None of these primary tumor characteristics should exclude a patient from consideration for surgical resection; however, they do identify patients who will be at increased risk for hepatic or extrahepatic recurrence.

The most important prognostic factors determining survival after hepatic resection appear to be those related to the *features and characteristics of the liver metastases*. These were examined in detail in the Hughes registry and by other institutional series.¹⁸⁸ Fong and colleagues²⁰⁴ have analyzed and summarized these characteristics thoroughly in their review of the literature. Although controversy exists as to the influence of tumor size, disease-free interval, and number of metastases on survival, most authorities agree that the ability to achieve a pathologic-negative margin of resection and the absence of extrahepatic metastases are clearly the most important survival determinants.²⁰⁵ Some studies have shown that patients with large (>5 cm) metastases appear to have a worse prognosis than patients with smaller tumors. Survival benefit has been seen in resection of these large lesions predicated on the ability to achieve tumor-free margins of resection. Thus, size in and of itself does not preclude resection but may make the ability to achieve free vascular or parenchymal margins problematic. Similarly, it was previously thought that patients with multiple metastases should not undergo liver resection. In their review, Fong and colleagues²⁰⁴ suggested that patients with three or fewer liver metastases may have a survival advantage compared with patients undergoing resection of four or more metastatic deposits. Survival differences between patients undergoing resection of a solitary metastasis and those with two or three lesions is not as clear-cut. Similar to the argument regarding tumor size, the actual number of liver metastases does not appear to be the major factor limiting resection; however, as the number of metastatic deposits within the liver increases, the ability to achieve a margin-negative resection becomes impaired, as does the ability to preserve enough normally functioning liver.^{198,202}

Because of these concerns, the location and distribution of multiple lesions and the extent of liver resection have been examined as prognostic variables. In the Hughes registry, the distribution of metastases comparing unilobar versus bilobar disease was not thought to be a significant predictor of survival. This has become an important factor with the advances in nonanatomic liver resections. With a greater understanding of hepatic segmental anatomy, more limited liver resections are now being performed. This allows a reduction in the amount of normal liver resected as well as resection of disease from both lobes. In treatment of lesions less than 4 cm in diameter, no differences in survival are seen between more limited segmental resections and formal hepatic lobectomies. Formal lobectomy may be required to obtain tumor-free margins in patients with large tumors. In patients with smaller tumors undergoing segmental resection, no difference in survival has been seen as long as clear pathologic margins are obtained.¹⁹³⁻²⁰²

The time interval between resection of the primary cancer and appearance of liver metastases seems to be a significant variable for survival. The 5-year survival rate for patients presenting with synchronous liver metastases was 27% in the Hughes registry.¹⁹⁸ Similarly, patients developing liver metastases within 12 months after resection of the primary colorectal cancer had a 5-year survival rate of 31%. This difference was

not significant. However, in patients developing hepatic metastases at an interval longer than 12 months, the 5-year survival rate after resection was 42%. This difference was significant and may reflect a biologically less aggressive tumor. Despite the adverse impact on survival, patients with otherwise resectable synchronous lesions should be considered for surgery.²⁰³

Another important variable affecting prognosis is the presence or absence of extrahepatic metastatic disease. Patients with celiac or hepatic lymph node metastases should not be considered for hepatic resection. The presence of such nodal disease is an indicator of systemic dissemination. Hughes and associates reported no 5-year survivors in 24 patients undergoing liver resection who were found to have positive intra-abdominal lymph node metastases.¹⁹⁸ More controversial is the role of resection of non-nodal extrahepatic metastases. Usually, this is thought to mean isolated pulmonary disease in the face of limited hepatic metastases. Although the number of patients who present with such limited pulmonary and hepatic metastases is small, there may be a role for resection in highly selected patients who demonstrate slow disease progression. In general, the presence of extrahepatic visceral metastases is a contraindication to liver resection. Despite our improved understanding of the prognostic variables related to long-term survival after liver resection, still the majority of patients will ultimately succumb to metastatic cancer. Most retrospective series demonstrate 5-year survival rates between 20% and 40% after resection for hepatic colorectal metastases.¹⁹³⁻²⁰⁴ Kanas's meta-analysis of numerous studies found 3-, 5-, and 10-year survival rates to be 57.5%, 38%, and 20%, respectively.¹⁸⁸

TYPES OF HEPATIC RESECTION

Wedge Excision

Wedge excision, the simplest hepatic resection, consists of non-anatomic removal of a small amount of superficial tissue. It is considered nonanatomic because the tissue does not correspond to any hepatic segment or subsegment.¹⁶⁸ The benefit of wedge resection is that it provides hepatic sparing, which is particularly important in patients who have decreased hepatic reserve.²⁰⁶

Subsegmentectomy

Subsegmentectomy is often difficult to perform because of the difficulty of exposure and vascular variability. For example, a solitary lesion in the caudate lobe is usually resected by removal of the medial and lateral segments of the left lobe to gain access to the lesion.^{168,203}

Right Hepatic Lobectomy

In this procedure (Figs. 91-17 and 91-18), the liver is mobilized, a cholecystectomy is performed, and the right branches of the bile duct, hepatic artery, and portal vein are dissected, ligated, and divided while avoiding injury to branches of the left lobe. The surgical plane is lateral to the middle hepatic vein, which must be left intact to provide drainage for the medial segment of the left lobe.^{168,207}

Right Trisegmentectomy

The entire right lobe and medial segment of the left lobe are removed by hilar dissection with ligation and division of the right lobe vessels plus the vessels to the medial segment. The right and middle hepatic veins are removed in this resection.

Figure 91-17 Traumatic hepatic injuries: types and treatment. **A.** Blunt injury in which a large defect involves the full thickness of the dome of the liver. **B.** This is treated by resectional débridement and individual vessel ligation. A less severe injury (**C**) requires only control of individual bleeders (**D**). (**A-D** from Madding GF, Kennedy PA: *Trauma to the Liver*, 2nd ed. Philadelphia, WB Saunders, 1971.)

The line of resection is just to the right of the falciform ligament, ensuring that the ascending portion of the portal vein is preserved. This extensive resection, although relatively safe for younger patients, should be used with caution in patients older than 65 years as the associated operative mortality rate is 30.7%.¹⁶⁰

Left Hepatic Lobectomy

During left hepatic lobectomy, the left lobar branches of the hepatic artery are ligated and divided in the hilum. The left hepatic veins are usually resected as well. The caudate lobe may be removed along with the left lobe or left in place. The surgical plane is just to the left of the middle hepatic vein, which must remain intact to drain the anterior segment of the right lobe.^{168,208}

Left Lateral Segmentectomy

This procedure is technically easier than the other forms of hepatic resection because hilar dissection is usually not needed. The surgical plane is just to the left of the umbilical fissure, so that the ascending portion of the portal vein is left intact. Much of the left hepatic vein can be resected because the medial segment of the left lobe is drained by the middle hepatic vein.

Left Trisegmentectomy

Left trisegmentectomy is a technically difficult procedure in which both segments of the left lobe and the anterior segment of the right lobe are resected. The right hepatic vein needs to be preserved to drain the remaining posterior segment.

Right Posterior Segmentectomy

This procedure is also technically difficult. The posterior segment of the right lobe is resected, leaving the right hepatic vein intact to drain the anterior segment.²⁰⁹

Minimally Invasive Hepatic Resection

The first laparoscopic procedure was performed 25 years ago. For years, laparoscopy in the abdomen was confined to cholecystectomy, but its role has greatly expanded thanks to technological advances, and it can now be used for numerous indications. The use of minimally invasive surgery in the liver has also soared. Minimally invasive surgery in the liver includes pure laparoscopic resection, hand-assisted laparoscopic resection, laparoscopy-assisted open resection (hybrid), and most recently robotic surgery. There are now numerous studies that have validated the use of laparoscopy in benign and malignant liver resections.²¹⁰⁻²¹⁴ Laparoscopically assisted resections generally result in lower operative times, less blood loss and less transfusion requirement, decreased length of stay in the hospital, and decrease in overall operative complications and recurrence of local malignant disease. Robotic surgery is the newest of the minimally invasive techniques and may be the most promising, allowing surgeons to compensate for inherent limitation of conventional laparoscopy by providing better ergonomics, visibility, and more articulating arms. Initial results demonstrate its feasibility in resection of benign and malignant hepatic lesions; however, further study is needed to validate outcomes relative to conventional laparoscopy as well as long-term oncologic follow-up outcomes.^{215,216}

Liver-Directed Therapy

Although hepatic resection and liver transplantation have good 5-year survival rates, more than 80% of patients are not surgical candidates and are deemed unresectable.²¹⁷ Liver-directed therapies offer viable treatment options for these patients. The most commonly used techniques currently are cryoablation, radiofrequency ablation, and intra-arterial therapies, including transarterial chemoembolization and radioembolization.

CRYOSURGERY

Cryosurgery refers to the in situ destruction of liver tumors by precise and rapid cooling of the tumor and a zone of normal hepatic parenchyma to extreme subzero temperatures. By circulation of a coolant such as liquid nitrogen through the core

of the tumor, temperatures as low as 100°C can be achieved. The effect of such profound hypothermia on tissue results in both indirect and direct mechanisms of cell destruction. Details of the lethal effects of cryosurgery have been well described by Ravikumar and colleagues²¹⁸ but essentially involve the formation of intracellular ice crystals leading to protein denaturation and rupture of cell membranes. Indirectly, subzero temperatures result in microvascular thrombosis and tissue anoxia. Further damage occurs if the cells are allowed to slowly thaw and are then rapidly refrozen. Clinical studies have suggested that two such freeze-thaw cycles may be necessary for optimal tissue destruction. Fundamental to the implementation of cryosurgery as a viable treatment option for patients with unresectable liver metastases has been the development of intraoperative ultrasound and refinement of equipment used to deliver the coolant to the tumor.

Early reports demonstrated the feasibility and safety of treating liver metastases by cryosurgery, whereas follow-up series have now helped define the indications for this modality.²¹⁸ The most significant clinical limitation of surgical resection is usually the number of lesions that can be safely removed while sparing sufficient hepatic parenchyma to avoid postoperative liver failure. Thus, the major indications for cryosurgery are either primary or metastatic lesions that are not amenable to resection because of cirrhosis or bilobar involvement in which either the number of lesions or the location of the tumors would risk sufficient postoperative hepatic function after resection.²¹⁸ For colorectal metastases, most centers with sufficient cryosurgical experience will limit this technique to patients with six or fewer metastases (generally <40% of the liver volume) and tumors smaller than 6 to 8 cm in greatest diameter and avoid large central tumors near the hilum of the liver. Similar to other forms of liver-directed therapy, cryosurgery probably offers little advantage to patients with extrahepatic metastatic disease. Operative technique currently involves intraoperative ultrasound localization and monitoring of the cryoprobe placement into the tumor.²¹⁹ In addition, intraoperative ultrasound allows detection of tumors not recognized on preoperative scans and is essential for monitoring of the freeze margins of the ice ball. The cryoprobes are vacuum-insulated devices that circulate supercooled liquid nitrogen through the probe's tip. A 3-mm blunt-tipped probe creates a freeze zone up to 4 cm, and the 8-mm trocar point probe creates a freeze zone of up to 6 cm. A single probe or combination of probes can be used to achieve complete freezing of the tumor and an additional 1 cm beyond the margin to ensure complete cryoablation. The entire process of probe introduction, freeze-thaw cycles, and probe extraction is monitored with real-time intraoperative ultrasound. Major complication rates are reportedly between 10% and 20%, and mortality rates are less than 2%.²¹⁸⁻²²⁰ Complications may

include hemorrhage, biliary fistula, hepatic or subphrenic abscess, and, more rarely, hepatic failure, coagulopathy, and cardiac arrest.²¹⁹⁻²²¹ Disease-free survival rates and patterns of failure have now been reported from several centers. With median follow-up times between 18 and 36 months, most series report 5-year actuarial disease-free survival rates between 15% and 28%.^{219,220}

RADIOFREQUENCY ABLATION

Radiofrequency ablation (RFA) refers to the direct thermal (heat) application (>80°C) to tumors with the intent of achieving cellular kill. The mechanisms of action of RFA include tissue heating, protein denaturation, release of water vapor, mechanical tissue destruction, breakdown of cellular membranes, and vascular thrombosis.²²³

Several studies have been performed demonstrating the effectiveness of RFA in achieving local tissue destruction, and it is now an accepted means of liver-directed therapy in those patients who have been excluded from surgical resection.^{222,224} The limitation continues to be disease progression at the margin of the ablated zone as well as outside the treatment field.^{225,226}

RFA can be accomplished by percutaneous, laparoscopic, or intraoperative means. Intraoperative ultrasound is an essential tool in the live identification of lesions intraoperatively that might not have been seen by standard cross-sectional imaging techniques. Indications for RFA include primary and metastatic liver tumors, renal tumors, osteoid osteoma, painful bone metastases, and lung tumors as well as adjunct to surgery in cases of surgical debulking for neuroendocrine tumors. Complications include bleeding, pneumothorax, biliary and vascular injury, and track seeding^{223,227,228} (Figs. 91-19 and 91-20).

Figure 91-19 Use of RFA for colorectal metastasis in a patient who has had prior radioembolization. A. T1-weighted MR image shows an enhancing lesion in the right lobe of the liver (arrow). Other nonenhancing lesions are compatible with prior treatment. **B.** Post-RFA image shows necrosis consistent with good response (arrow). **C.** Post RFA T1-weighted MR image reveals a thin ring of enhancement (arrow) that is often seen after therapy and is benign, thought to represent fibrosis.

Figure 91-20 Use of percutaneous RFA for metastasis. **A.** Post-contrast CT shows a small, peripherally enhancing lesion consistent with metastatic disease (arrow). **B.** Intraprocedural noncontrast CT shows the RFA prongs within the lesion (arrow). **C.** Post-RFA CT image shows the lesion to be larger than the original but without any enhancement, consistent with necrosis and good response (arrow). Size criteria for tumor response may be misleading in liver-directed therapy, and lack of enhancement of the lesion should be the main interpretative criterion.

CHEMOEMBOLIZATION

Chemoembolization exploits the preferential blood supply provided by the hepatic artery to neoplastic lesions.²²⁹⁻²³¹ Initial attempts at ligation of the hepatic artery resulted in temporary regression of hepatic tumors. The effect was transient because of the rapid development of collateral vessels distal to the ligated vessels.²³² Chemoembolization is performed by placing a catheter into the hepatic artery, followed by concomitant local delivery of chemotherapy and a vascular occlusion agent. The dual injection results in theoretical benefits above those obtained with either procedure alone. In addition to the ischemic damage created by the embolization agent, the vascular occlusion results in more confined and prolonged exposure of the chemotherapeutic agent.^{233,234} Anoxic damage also causes increased vascular permeability with increased infiltration of the tumor with chemotherapy.²³³ Finally, cytotoxic irritation of the vessel may result in an irritant vasculitis, leading to further occlusion and ischemia.²³³ Although there is increased local toxicity with the combination of treatments, systemic toxicity is minimized by drug metabolism during first passage through the liver.²³⁵ Clinical trials have demonstrated significant and sustained responses to chemoembolization in the treatment of unresectable primary hepatomas, metastatic colorectal cancers, and neuroendocrine tumors. In 2002, two landmark publications demonstrated the survival advantage incurred by chemoembolization in patients with intermediate-stage hepatoma. These papers helped establish chemoembolization as the worldwide “gold standard” for treatment of hepatoma.^{236,237} In 2006, Takayasu and colleagues²³⁸ published data from 8510 hepatoma patients treated with chemoembolization and found 1-, 3-, 5-, and 7-year survival rates of 82%, 47%, 26%, and 16%. In summary, the mechanisms of action of chemoembolization include application of chemotherapy directly into the tumor bed and reduction of the blood

supply to the tumor. These have the additive effect of increasing chemotherapeutic concentration within the applied area, increasing dwell time, and reducing systemic toxicity.

Embolization is accomplished by use of a viscous liquid, such as Lipiodol,²³⁹⁻²⁴⁶ or particulate matter, such as Ivalon polyvinyl particles,^{247,248} collagen particles,^{249,250} starch microspheres,²⁵¹⁻²⁵⁵ or steel coils.²⁵⁶ Although some of these agents have special properties, they have not been directly compared. Lipiodol, for example, has been shown to be taken up preferentially by hepatocellular carcinoma tumor cells. Chemotherapeutic agents that have been used for this procedure include 5-fluorouracil, floxuridine, mitomycin C, cisplatin, and doxorubicin. The independent relative effectiveness of these agents has not been determined.

Complications of chemoembolization include postembolization syndrome (pain, nausea, fever), elevated liver function test results, liver infarction, abscess formation, cholecystitis, renal and cardiac failure, and death. The likelihood of hepatic infarction is particularly elevated in patients undergoing chemoembolization in the presence of portal vein thrombosis. Hepatic abscess formation is of particular concern in patients with an incompetent ampulla of Vater (e.g., biliary stents) or in patients with a hepaticocenterostomy.^{257,258}

Conventional radiologic techniques may actually not be adequate to assess response to therapy. Although changes that are consistent with liquefaction necrosis may be seen up to 1 month after chemoembolization, maximal decrease in tumor volume is obtained with scans performed 2 to 3 months after the procedure.²⁵⁰ Carcinoembryonic antigen and α -fetoprotein measurements for colorectal cancers and hepatoma may be used for clinical follow-up.

The goals of chemoembolization are to improve symptom control and to increase disease-free and overall survival. Chemoembolization in conjunction with systemic chemotherapy

Figure 91-21 Use of chemoembolization in hepatic metastases. **A.** T1-weighted fat-saturated postcontrast MR image reveals an enhancing lesion in the right lobe of the liver (arrow). **B** and **C.** Intraprocedural angiogram reveals tumor blush in two lesions that is then obliterated after embolization (arrows). **D.** CT scan shows high-density material that is typically seen after chemoembolization, representing Lipiodol (arrow, arrowhead) in the dominant and smaller satellite lesions. This should not be confused with enhancement. **E.** Postcontrast T1-weighted fat-saturated MR image shows lack of enhancement consistent with tumor necrosis (arrow).

may yield better results than either modality alone. Clinical parameters that predict response to treatment and survival, such as tumor vascularity and extent of liver involvement, can be used to select patients most likely to benefit from regional chemotherapy. Earlier detection and referral of patients with low-volume hepatic disease may improve outcome (Fig. 91-21).

COMBINATION CHEMOEMBOLIZATION AND RADIOFREQUENCY ABLATION

Given the effectiveness of chemoembolization and RFA as single therapeutic modalities, there has been recent interest in combining the two in an attempt to further improve efficacy. The theory of applying both in combination is analogous to the surgical Pringle maneuver: impairing blood flow to tumor (chemoembolization) with the simultaneous application of ablative heat (RFA). Results combining these therapies have been promising, with recurrence-free time of 12.5 months, more than 70% improvement in tumor markers, and complete necrosis in more than 90% of tumors.²⁵⁹

RADIOEMBOLIZATION

Radioembolization represents a newer transarterial therapy for liver malignant neoplasms. It is defined as the intra-arterial administration of radiation by an embolization vehicle. This technology capitalizes on the fact that hepatic tumors derive their blood supply from the hepatic artery rather than from the portal vein. Hence, radioembolization allows the administration of microscopic radiation particles to be delivered

preferentially to the tumor with concomitant embolization of the feeding artery.²⁶⁰

Although there have been some preliminary case reports on the use of rhenium and holmium microspheres, the most common radioembolic microsphere clinically in use is yttrium 90. Yttrium 90 is a beta emitter with a half-life of 64.2 hours. The microspheres are carried by glass or resin as the embolic carrier and range between 20 and 60 μm . They are preferentially carried by hypervascularity to tumor, where they exert their local radiation effect. This technique of radioembolization allows the administration of high absorbed doses to hepatic tissue (>200–300 Gy). This dose would not be tolerated well systemically, but the transarterial administration allows this level of radiation. The microspheres are selectively administered by percutaneous access to the hepatic artery on a whole liver, lobar, segmental, or subsegmental level.^{261–263} The use of yttrium 90 microspheres has been studied in primary and secondary metastatic tumors to the liver. With hepatoma, radioembolization has been shown to be safe and effective and, as well, to permit downstaging to resection and liver transplantation. Survival in patients with hepatoma is reported to be approximately 700 days for Okuda stage I patients. In patients with metastatic disease to the liver, survival rates range between 7 and 10 months in patients who have failed to respond to standard of care polychemotherapies.^{263–271} Sato and colleagues²⁷² studied radioembolization in patients with unresectable chemorefractory liver metastases who had few treatment options left and found that 87% of lesions demonstrated a halting or reversal of progression. Salem and coworkers²⁷³ published their experience with 463 patients with hepatocellular

carcinoma and found that compared with chemoembolization, radioembolization resulted in longer time to progression and less toxicity. These promising data are quickly making radioembolization the liver-directed therapy of choice in some institutions (Fig. 91-22).

POSTOPERATIVE RADIOLOGIC APPEARANCE OF THE LIVER

CT and MRI are the preferred means of postoperative evaluation of the liver.²⁷⁴ The appearance of the postoperative liver depends on what segment is resected, what operation is performed, the degree of hepatic regeneration, and the

presence and nature of postoperative complications. Baseline postoperative scans are essential for future evaluation of recurrent hepatic malignant disease.²⁷⁴

After resection of the right lobe, hypertrophy of the left lobe occurs with displacement of the ligamentum teres and falciform ligament to the right (Fig. 91-23). The caudate lobe also modestly enlarges, with the portal vein displaced posteriorly, so that the porta hepatis is exposed dorsally to the anterior aspect of the right renal fascia. Other common findings include migration of the colon and the small bowel into the hepatic fossa, elevation of the right kidney, posterior displacement of the inferior vena cava, and elliptical enlargement of the remaining liver.²⁷⁵

Figure 91-22 Use of radioembolization in the treatment of a small hepatoma. **A.** Chemical shift MR image shows a drop in signal intensity on the out-of-phase image (arrow) consistent with fat. **B.** Postcontrast T1-weighted fat-saturated MR image shows the lesion to arterially enhance (arrow). This lesion also had washout of contrast material and was consistent with a hepatoma. **C.** After radioembolization, the image reveals necrosis consistent with favorable treatment response and a thin rim of enhancement that is postprocedural fibrosis and benign (arrow).

Figure 91-23 Postoperative liver: CT findings. **A.** Typical CT appearance after right hepatic lobectomy. There is hypertrophy of the medial segment (MS) and lateral segment (LS) of the left lobe and caudate lobe (CL). Elevation of the right kidney (RK), posterior displacement of the inferior vena cava (arrow), and migration of colon (C) into the hepatic fossa are seen. **B.** This patient had a trisegmentectomy with construction of a greater omental pack (OP) along the lateral aspect of the remaining lateral segment of the lobe. The patient developed a recurrent tumor, accounting for the intrahepatic biliary dilation.

After left lobectomy, the right lobe enlarges in a rounded shape, with displacement of the porta hepatis and portal vein to the left and inferior displacement of the right kidney. The stomach or colon occupies the left hepatic fossa.²⁷⁵

Partial hepatectomy is often accompanied by a small region of low attenuation near the plane of dissection, which is due to fatty infiltration, fibrous tissue, and hepatocytes laden with bile pigment, presumably representing the sequelae of local trauma.²⁷⁴⁻²⁷⁶ These changes are transient and must be differentiated from abscess and hematoma. Hypertrophy of the hepatic parenchyma can be seen on CT scans as a progressive change in contour of the hepatic parenchyma during a period of 6 months to 1 year.²⁷⁵

The greater omentum is often swung up to the operative site to provide natural “packing” material that helps diminish the frequency of postoperative complications (see Fig. 91-23). The fat in the omentum can simulate a low-density mass lesion, so knowledge of the operative technique is useful in its identification.²⁷⁷ In the early postoperative period, there can be transient fluid that accumulates between the omental pack and the resection margin. This fluid contours with the liver margin and can be differentiated from a focal collection such as a biloma or abscess.²⁷⁴ MR can be particularly useful when CT is limited by streak artifacts caused by surgical clips or is contraindicated because of inability to intravenously administer iodinated contrast material. Regenerated liver has the same signal intensity as normal liver. Diffuse inhomogeneity of the hepatic parenchymal signal can be seen after chemotherapy and may be related to fatty infiltration or vascular damage. These irregular, ill-defined areas are in contrast to recurrent tumor, which generally has more sharply margined regions of high signal intensity on T2-weighted images.²⁷⁸ MR may be helpful in differentiating postoperative hematoma from other focal fluid collections on the basis of the signal intensity of methemoglobin.²⁷⁹

Most hepatic regeneration occurs within 6 months, but the process may take more than 1 year.

Complications

Complications resulting from hepatic surgery are similar to those of other major abdominal operations: abscess, hemorrhage and hematoma, and pleural effusions.²⁸⁰ Biloma and hematoma are fairly common owing to the nature of the surgery and the biliary and vascular structures transected. Surgical complications occur in 25% to 30% of hepatic operations and are best diagnosed and nonoperatively treated with CT.^{274,281,282} Hepatobiliary scintigraphy (Fig. 91-24) and Doppler ultrasound may be needed to help clarify biliary and vascular complications.

POSTPROCEDURAL RADIOLOGIC APPEARANCE OF THE LIVER

Imaging of the liver after liver-directed therapy is critical in assessing response to treatment. This imaging is best performed with either CT or MRI. The normal post-therapy appearance of the liver can be confusing. An understanding of the appearance of hepatic tumors treated with liver-directed therapies is crucial in differentiating normal postprocedural changes from residual and recurrent tumor.

Figure 91-24 Postsurgical bile leak. Bile leak followed focal excision of a hepatic mass in the left lobe. This diisopropyliminodiacetic acid-enhanced hepatobiliary scan shows leakage of bile-containing isotope (curved arrow) that extends into the left subphrenic space (straight arrow).

The conventional means of assessing tumor response by a size decrease according to the World Health Organization or RECIST (Response Evaluation Criteria in Solid Tumors) assessment often does not accurately predict response. Although, with time, the lesions treated with liver-directed therapies decrease in size on early post-therapy scans, there is often an increase in size that should not be construed as progressive disease.²⁸³⁻²⁸⁵ It is the intermediately timed post-therapy scans performed at 2 to 3 months that often begin to show the greatest reduction in tumor volume.²⁸³⁻²⁸⁵ The hallmark of positive response to chemoembolization, radiofrequency ablation, and any of the liver-directed therapies is loss of enhancement on postcontrast imaging. This absence of enhancement correlates with tumor necrosis and can be seen on imaging shortly after therapy (less than 1 month). At times, a thin, peripheral rim of enhancement may be visualized normally, which does not represent residual tumor but is likely to relate to inflammatory or fibrotic response. Areas of nodular peripheral enhancement or a thick rim of enhancement in a treated lesion should be viewed as suspicious for residual or recurrent malignant disease.²⁸⁶ In fact, the modified RECIST criteria incorporate assessment of residual viable tumor by measurement of the longest diameter of only the enhancing part of the tumor, not the necrotic portion.²⁸⁷ In addition, global enhancement assessment of the entire lesion should be performed to determine if there is significant enhancement. As enhancement is one of the main determinants of tumor response, it is important to perform contrast-enhanced CT or MR examinations with precontrast imaging in patients who have undergone chemoembolization. On the precontrast images, the lesion often has high density. This should not be

confused with calcification but actually represents the density of the chemoembolization agents (see Fig. 91-21D). Without precontrast images, this finding could potentially be confused with contrast enhancement. In addition, chemoembolization can cause changes in the adjacent normal liver parenchyma, resulting in low-attenuation regions corresponding to areas of ischemia or infarction.²⁸⁸

The appearance of the liver after cryosurgery can vary slightly from the appearance with other therapies. Here, because the freeze zone is often larger than the original lesion, the resultant post-therapy low-attenuation lesion is often significantly larger. These lesions can appear rounded, oval, or wedge shaped. They can contain foci of air and hemorrhage as well. As in the other liver-directed therapies, a thin peripheral rim of enhancement may be seen.²⁸⁹

The newest liver-directed therapy, radiotherapy with yttrium 90 microspheres, can cause some unique post-procedural imaging changes.²⁹⁰ As with the other therapies, the lack of enhancement reflects the positive response consistent with tumor necrosis (Fig. 91-25). The lesion may initially be unchanged in size or perhaps even slightly increased, but lesion volume usually decreases on subsequent imaging. Again, lack of enhancement suggesting necrosis is the hallmark of positive response, but this can occur more slowly with radioembolization than with other techniques. In this scenario, diffusion-weighted MRI can sometimes predict a favorable response before the visualization of necrosis on imaging²⁹¹ (Fig. 91-26). Whereas solid tumors demonstrate increased cellularity and restricted diffusion, treated lesions contain necrotic tissue with

compromised cell membrane integrity and decreased cellularity. This will result in less diffusion restriction and can predate the loss of enhancement and necrosis seen on MR. Thus, diffusion-weighted MR can sometimes predict a favorable response before the hallmark of necrosis on MR, which can be an invaluable tool in the MR armamentarium of the radiologist. As with other liver-directed therapies, a thin ring of enhancement surrounding the lesion often occurs and should not be interpreted as viable tumor but instead likely represents inflammatory or fibrous tissue.

Within the adjacent tumor-free liver parenchyma, attenuation changes can occur.²⁹² These areas often appear hypointense or hypodense and prominent and heterogeneous. These attenuation alterations can be confused with tumor, but they do not typically enhance. They are thought to represent perivascular edema, congestion, and microinfarction from the radiation exposure. These hypoattenuation areas have been found to be more heterogeneous with lower radiation doses and more diffuse with higher doses. These changes tend to dissipate on later scans (4 months), suggesting that they are reversible.²⁹³ More chronic findings of capsular retraction, parenchymal enhancement, and hepatic fibrosis can occur and are thought to arise from radiation effect on the hepatic parenchyma (Fig. 91-27). There can also be extrahepatic effects of the yttrium radioembolization on the biliary tree, hepatic vessels, gallbladder, duodenum, and stomach, causing radiation ischemia and necrosis (Fig. 91-28). Biliary sequelae can include biliary necrosis, resulting in strictures and bilomas, as well as cholecystitis.^{294,295}

Figure 91-25 Effect of yttrium treatment on hepatocellular carcinoma. **A.** T1-weighted postcontrast MR image reveals a small enhancing hepatocellular carcinoma (arrow). **B.** Radioembolization shows a tumor blush (arrow). **C.** Image after radioembolization reveals the lesion to be larger with minimal enhancement (arrow). Full effect of radioembolization may take longer than in other liver-directed therapies. **D.** Follow-up MRI demonstrates complete nonenhancement compatible with tumor necrosis (arrow).

Figure 91-26 Use of diffusion-weighted MRI to predict treatment response. **A.** T2-weighted image shows an exophytic mass from the right lobe of the liver (arrow). **B.** T1-weighted postcontrast image reveals that this mass enhances; it was found to be a hepatoma (arrow). **C.** Diffusion-weighted MRI reveals low signal, suggesting restricted diffusion (arrow). **D.** MR image early after radioembolization shows some persistent enhancement (arrow). **E.** Diffusion-weighted MR, however, reveals increased signal and less restricted diffusion (arrow), which suggests a favorable response to radioembolization despite the persistent enhancement. The diffusion images were able to predict a positive response before the contrast images.

Figure 91-27 Effect of radioembolization on the adjacent hepatic parenchyma. **A.** MR image shows a small enhancing hepatoma (arrow). **B.** Close follow-up post-therapy image shows ill-defined enhancement of adjacent parenchyma in a vascular distribution (arrow), suggesting perivascular edema and inflammation. An incidental hemangioma is seen (arrowhead). **C** and **D.** Follow-up MR images reveal the lesion as a much smaller nonenhancing focus, suggesting excellent treatment response (arrowheads). The adjacent parenchyma enhances in a delayed fashion with capsular retraction (arrows), suggesting hepatic fibrosis from radiation effect.

Figure 91-28 Complication of radioembolization. **A.** A postcontrast chest CT of a patient who was status post radioembolization reveals pooling of contrast material, suggesting a pseudoaneurysm (arrow). **B.** Angiogram confirms several small pseudoaneurysms (arrow), which were thought to be radiation induced. They were successfully embolized.

Summary

Orthotopic liver transplantation (OLT) is the only definitive treatment of end-stage liver disease. About 6000 liver transplants are performed annually in the United States. Lack of donors remains a huge challenge for liver transplantation programs. Of the 15,641 patients on the waiting list for liver transplantation in 2009, 2396 patients died waiting for a transplant.¹ The first human liver transplant was performed in 1963 by

Thomas Starzl. The surgical technique and management of patients with liver transplant significantly improved during the next few decades. Increasing experience has resulted in current 1-, 3-, and 5-year survival rates of 87%, 78%, and 73%, respectively. Early graft failure within 6 weeks of transplantation in deceased donors has decreased from 6.9% in 1998 to 3.0% in 2009.¹

In 1987, Congress passed the National Organ Transplant Act, which established the Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients. OPTN links all professionals involved in the organ donation and transplantation system. The United Network for Organ Sharing (UNOS) is the OPTN contractor that coordinates the nation's transplant system. UNOS maintains the national organ transplant waiting list, increases awareness of organ donation, develops policies and standards for transplantation, and monitors members for compliance.

Indications for Liver Transplantation

The indications for OLT are presented in [Table 92-1](#).

HEPATITIS C

Chronic liver disease caused by hepatitis C virus infection is the leading cause of liver transplantation. Unfortunately, reinfection of the allograft by the hepatitis C virus is universal. Reinfection results in faster progression to fibrosis and cirrhosis compared with the nontransplant population. Cirrhosis develops in 25% of recipients within 5 to 10 years of transplantation.² Graft failure rate at 10 years is higher in patients with hepatitis C (45%) compared with the rate for all deceased donors (51.3%).

ALCOHOLIC LIVER DISEASE

Patients who undergo liver transplantation for alcoholic liver disease have outcome similar to that of patients receiving transplants for nonalcoholic disease. However, studies have shown that 10% to 15% of patients receiving transplants for alcoholic liver disease resume heavy drinking, which can harm the transplant. UNOS suggests at least 6 months of abstinence before transplantation (6-month rule). This effectively eliminates patients with acute alcoholic hepatitis from receiving transplants.³

MALIGNANT DISEASE

Hepatocellular carcinoma (HCC) occurring in the setting of cirrhosis is a common indication for transplantation. Cholangiocarcinoma, hemangioendothelioma, and hepatoblastoma are much rarer indications for transplantation.

TABLE 92-1
Indications for Orthotopic Liver Transplantation in the United States (2009)

Primary Cause of Disease	Percentage
Hepatitis C	25.6
Malignant disease	18.7
Alcoholic liver disease	17.4
Cholestatic disease	7.9
Acute hepatic necrosis	4.3
Metabolic liver disease	2.5
Others (nonalcoholic steatohepatitis most common)	23.6

NONALCOHOLIC STEATOHEPATITIS

Nonalcoholic fatty liver disease represents a spectrum of liver disease due to triglyceride accumulation in the hepatocytes ranging from benign steatosis to nonalcoholic steatohepatitis (NASH), fibrosis, and cirrhosis. As a consequence of the growing epidemic of obesity, nonalcoholic fatty liver disease and NASH have a prevalence of 30% and 12%, respectively, in the U.S. population. NASH represents a rapidly growing indication for liver transplantation in the last decade.⁴ It is currently the third most common cause of transplantation. In 2009, NASH was listed as the primary indication for 8.5% of liver transplants compared with 1% in 2001.⁵ These numbers are likely to underestimate the true incidence of NASH as underlying steatosis often dissipates after the development of cirrhosis. A substantial portion of patients with cryptogenic cirrhosis listed as the indication for transplantation probably had NASH.⁵

CHOLESTATIC LIVER DISEASE

Primary biliary cirrhosis and primary sclerosing cholangitis are the most frequent cholestatic conditions in adults, and liver transplantation is an excellent option for patients who progress to end-stage disease. Transplantation for cholestatic disease has better survival rates than many other indications. Biliary atresia, cystic fibrosis, and Alagille's syndrome are cholestatic conditions in children that can be treated with transplantation.⁶

ACUTE HEPATIC NECROSIS

Acute hepatic necrosis or acute liver failure is characterized by sudden massive necrosis of hepatocytes and has very high mortality. Liver transplantation provides the most definitive treatment of acute liver failure. Viral hepatitis and drug toxicity (including acetaminophen) are common causes.⁷

METABOLIC DISEASE

Wilson's disease, hereditary hemochromatosis, and α_1 -antitrypsin deficiency are metabolic diseases that can cause irreversible hepatic damage.

Patient Evaluation for Liver Transplantation

LISTING AND TIMING OF LIVER TRANSPLANTATION

The demand-supply situation for liver transplantation is such that a large number of patients are waitlisted for a small number

of available organs. Before 2002, patients received transplants on a first-come, first-served basis. However, the sickest patients in the most urgent need of transplantation were not always the first on the list, and death on the wait list increased. The optimal timing of liver transplantation should be such that a patient must be sick enough to require a transplant but not be so sick as to be unable to withstand the transplantation. Comorbid conditions (like HCC) should not be allowed to advance so much that survival of the graft or of the patient is affected. The MELD score and Milan criteria are used to evaluate the need of transplantation.

MODEL FOR END-STAGE LIVER DISEASE (MELD) SCORE

The MELD score is a predictor of short-term mortality in patients with chronic liver disease. It is calculated from serum creatinine concentration, international normalized ratio, and bilirubin concentration. Since 2002, UNOS has used the MELD score to assess the acuity of need for liver transplantation. Patients with high MELD scores have more urgent need of transplantation and are placed higher in the list irrespective of their time of listing.

HEPATOCELLULAR CARCINOMA AND LIVER TRANSPLANTATION

HCC commonly arises in cirrhotic livers, particularly in patients with hepatitis B and C. Liver transplantation can potentially treat the underlying liver disease as well as the HCC. The selection of patients with HCC for liver transplantation is complicated. Patients with advanced HCC who undergo transplantation have shown disease recurrence and poor survival.⁸ In view of donor liver shortage, transplantation for patients with advanced HCC is not advisable as scarce organs could be directed to patients more likely to benefit from the transplant.

Patients with HCC may not have such poor synthetic function (or high MELD score) to qualify for a liver transplant. As these patients wait for their liver function to deteriorate enough to qualify for transplantation, the underlying HCC may advance such that the patient is no longer a good candidate for transplantation because of the risk of HCC recurrence.

To deal with this problem, UNOS/OPTN does not allow transplantation in patients with advanced HCC by the Milan criteria and gives exception points (based on certain criteria) to patients with limited HCC for additional priority for liver transplantation.

MILAN CRITERIA

The Milan criteria (Table 92-2) are used to identify patients with HCC in whom the tumor burden is small enough to allow good outcome after liver transplantation. The Milan criteria state that transplantation should be performed in those with a single tumor of 5 cm or less or three tumors that are each 3 cm or less, no macrovascular invasion, and no metastasis. Patients who do not meet the Milan criteria are not considered eligible candidates for liver transplantation. Some authors have suggested that the Milan criteria are too restrictive and that acceptable outcomes can be obtained with more liberal tumor criteria (e.g., University of California, San Francisco, criteria).⁹

MELD EXCEPTION POINTS FOR HEPATOCELLULAR CARCINOMA

For patients within the Milan criteria, UNOS/OPTN grants exception points to stage T2 HCC (one tumor ≥ 2 cm and ≤ 5 cm or two or three tumors ≥ 1 cm and ≤ 3 cm). This allows these patients to undergo transplantation earlier in the course of their disease in an attempt to achieve better long-term survival after transplantation. The goal is to prevent the patient from reaching an HCC tumor burden that exceeds the Milan criteria, which would necessitate the patient's being removed from the transplantation waiting list.

Preoperative Imaging

The main objective of preoperative imaging is to provide the surgeon with the necessary information needed to plan and perform liver transplantation and to exclude patients for whom surgery either is not feasible or would be of no benefit. Preoperative radiologic evaluation is used to detect HCC or other malignant disease, to determine the size and patency of the

portal vein and superior mesenteric vein, to assess hepatic arterial inflow, and to evaluate surgical portosystemic shunts and location of varices.

EXCLUSION OF HEPATOCELLULAR CARCINOMA

Patients awaiting liver transplantation undergo contrast-enhanced computed tomography (CT) or magnetic resonance imaging (MRI) to screen for HCC. Ultrasound is used for routine screening of cirrhotics for HCC, but patients being considered for a transplant usually undergo CT or MRI. A multiphase technique with late arterial, portal venous, and delayed phases is used. HCCs derive their blood supply from the hepatic arteries and show hyperenhancement in the arterial phase. They "washout" or become hypoattenuating to the hepatic parenchyma in the portal venous and delayed phases. A peripheral rim of enhancement or "pseudocapsule" may be present on the portal venous or delayed phase (Fig. 92-1). Any hepatic lesion identified is classified by the OPTN classification system. The number and size of each HCC and the presence of any vascular invasion or metastatic disease are noted (Fig. 92-2).

TABLE 92-2 Description of OPTN Class 5 Nodules That Qualify as Hepatocellular Carcinoma for Exception Points		
Class	Size	
5A	≥ 1 cm but < 2 cm	Increased arterial enhancement and washout and pseudocapsule
5A-g	Same as 5A	Increased arterial enhancement and growth by 50% in 6 months
5B	≥ 2 cm but ≤ 5 cm	Increased arterial enhancement and either washout or pseudocapsule or growth by 50% in 6 months
5T	Prior locoregional therapy for HCC	Describes any residual lesion or perfusion defect at prior UNOS class 5 lesion
5X	> 5 cm	Meets criteria for HCC but outside stage T2 and not eligible for exception points

HCC, Hepatocellular carcinoma; OPTN, Organ Procurement and Transplantation Network; UNOS, United Network for Organ Sharing.

OPTN CLASSIFICATION SYSTEM FOR NODULES SEEN ON IMAGING OF CIRRHOTIC LIVERS

OPTN/UNOS has strict radiologic criteria for classification of nodules in cirrhotic livers as HCC. Only class 5 nodules are considered to meet radiologic criteria for HCC and may qualify for automatic exception, depending on stage (see Table 92-2).

PORTAL VEIN EVALUATION

The portal venous system can be assessed by Doppler ultrasound, CT, or MRI. Liver transplantation in patients with extrahepatic portal venous thrombosis or a small-caliber vein is difficult or sometimes impossible. The normal diameter of the extrahepatic portal vein is 8 to 12 mm. The extrahepatic portal vein usually needs to be at least 4 to 5 mm in diameter for a successful portal vein anastomosis. On Doppler examination, portal vein thrombosis is usually depicted as echogenic material within the portal vein. The extent of thrombus should be determined, and the entire extrahepatic portal vein and superior

Figure 92-1 HCC identified during pretransplantation evaluation. **A.** Arterial phase of contrast-enhanced MRI shows a hyperenhancing right hepatic lesion (arrow). **B.** A delayed image shows washout of contrast material from the tumor. A peripheral pseudocapsule is noted (arrowheads).

Figure 92-2 Infiltrating HCC with portal venous invasion. Venous phase MR image shows a large infiltrating HCC (arrow) with invasion of the portal vein (arrowhead). The large size and portal venous invasion exclude this patient from liver transplantation (Milan criteria).

mesenteric vein should be evaluated. Although extensive portal vein thrombus was considered a contraindication to OLT in the past, many patients can successfully undergo liver transplantation with modified surgical techniques. In these patients, evaluation of the superior mesenteric vein is critical. If the superior mesenteric vein is patent, placement of an interposition graft or venous jump graft from the superior mesenteric vein to the portal vein is a feasible option.¹⁰ The hepatic veins and inferior vena cava (IVC) also should be evaluated for patency.

HEPATIC ARTERY EVALUATION

Preoperative assessment of recipient hepatic arterial supply is important to ensure adequate hepatic arterial inflow to the transplanted liver. The arterial patency can be assessed on preoperative ultrasound, CT, or MRI. Inadequate hepatic arterial inflow usually results from compression of the celiac trunk by the arcuate ligament or from atherosclerosis. In patients with arcuate ligament compression, simple division of the ligament improves blood flow. Compromised arterial inflow resulting from atherosclerosis usually requires creation of either a supraceliac or an infrarenal aorto–hepatic artery bypass graft.

PORTOSYSTEMIC SHUNT AND VARICEAL EVALUATION

CT and MRI can precisely locate surgical and spontaneous portosystemic shunts and varices that may be encountered. In patients with cirrhosis, surgical portosystemic shunts are often created to decompress portal hypertension and varices to diminish the chance of gastrointestinal hemorrhage. When transplantation is performed, these surgical portosystemic shunts are often ligated so that portal flow to the allograft is not compromised. Likewise, the presence and location of varices are helpful to the surgeon. Varices that are encountered may be ligated. Alternatively, the surgeon may choose to avoid rather

than to ligate certain varices, thereby reducing the potential for hemorrhagic complications.

Locoregional Bridging Therapy for Hepatocellular Carcinoma

Locoregional therapies are used to treat HCC in patients on the transplant waitlist. These are used as bridge strategies with the primary goal of reducing tumor progression to allow patients to be longer on the waitlist. Although bridge strategies are widely used, it is not clear whether they are effective in maintaining patients on the list or improving disease-free survival.^{11,12}

Image-guided transcatheter delivery of therapeutic agents through vessels feeding the HCC is a commonly used bridge therapy that allows more focused delivery of therapeutic material within the tumor. Conventional transcatheter arterial chemoembolization consists of intra-arterial infusion of a drug, such as doxorubicin or cisplatin with or without a viscous emulsion, followed by embolization of the blood vessel with gelatin sponge particles or other embolic agents. Recent advances include use of drug-eluting beads for more controlled and sustained drug release. Radioembolization by transcatheter infusion of microspheres coated with yttrium 90, a beta particle–emitting isotope, into feeding vessels allows delivery of high-energy, low-penetration radiation to the tumor.

Local ablation is a commonly used bridge therapy for small HCCs (single or few) that are accessible either percutaneously or laparoscopically. Multiple ablative techniques, including radiofrequency ablation, microwave ablation, cryoablation, and ethanol injection, are available. In patients with good hepatic function, surgical resection of a solitary HCC is also used as bridge therapy.¹³

Surgical Technique

The main steps of an OLT procedure consist of donor hepatectomy, recipient hepatectomy, hemostasis, and vascular anastomoses followed by biliary anastomosis. The caval anastomosis is the first vascular anastomosis performed. The standard and piggyback techniques are different methods to perform the caval anastomosis (Figs. 92-3 and 92-4). In the standard technique, the recipient's retrohepatic IVC is removed with the recipient's liver. End-to-end anastomosis is then performed twice between the donor and recipient IVC above and below the liver. In the newer piggyback technique, the recipient's IVC is not removed with the recipient's liver. The donor's suprahepatic IVC is anastomosed to the common orifice of the recipient's hepatic veins. The main advantage of the piggyback technique is that it preserves caval flow and reduces hemodynamic instability during the procedure.¹⁴

The portal venous and hepatic arterial anastomoses are done after the caval anastomosis. The portal venous anastomosis is an end-to-end anastomosis. The arterial anastomosis is often performed with a Carrel patch. In this, the donor hepatic artery is harvested at the level of the celiac axis with a patch of the aorta. The aortic patch is then anastomosed to the recipient hepatic artery near the gastroduodenal artery takeoff.

The biliary anastomosis is usually an end-to-end choledochocholedochostomy. A biliary–enteric anastomosis (choledochojejunostomy) is performed in recipients with bile duct

Figure 92-3 Diagram shows surgical anatomy of OLT by piggyback IVC anastomotic technique. The donor's suprahepatic inferior vena cava (IVC) is anastomosed to the common orifice of the recipient's hepatic vein (H.V.). There is an end-to-end hepatic arterial (H.A.) anastomosis of the recipient's hepatic artery near the gastroduodenal artery takeoff with the donor hepatic artery, which is harvested at the level of the celiac axis with a patch of the aorta. An end-to-end portal venous (P.V.) anastomosis and an end-to-end choledochobiliary anastomosis over a T tube are shown.

disease. Traditionally, biliary anastomosis has been performed with T-tube drainage, but some institutions have now moved away from routine use of T-tube drainage for deceased donors.¹⁵ Presence of a T tube allows monitoring of biliary output, supports the anastomosis, and allows access for cholangiography. Other than patient discomfort from prolonged presence of a percutaneous tube, the main limitation of T-tube placement is biliary leakage after its removal.

Shortage of donor organs, primarily in children awaiting a suitable liver for transplantation, has driven the development of reduced size, split liver, and living related donor transplantation techniques. These techniques increase the available supply of donor organs to younger recipients. Reduced size liver transplantation uses a portion of the liver as a graft but is an inefficient use of donor organs. Split liver transplantation, whereby the whole liver is used for transplantation for two recipients, is an attractive means of increasing the use of a limited supply of donor organs to both children and adults.¹⁶ Living related donor transplantation uses a portion of the donor liver. The lateral segment may be used successfully for small or pediatric patients with end-stage liver disease. A larger graft is needed for adult living donor transplantation, and whole right hepatic lobe grafts have been used successfully in many transplantation centers.¹⁷

Living Donor Liver Transplantation

The number of cadaveric donors available for liver transplantation has remained constant for several years. As thousands of patients are on the waiting list, living donor liver transplantation (LDLT) can be a solution for these patients. However, LDLT requires balancing donor risk relative to the recipient outcome and has not become popular in the United States. Only 219 LDLTs were performed in the United States in 2009, probably because of the risk of donor morbidity and mortality.¹ LDLT is more popular in countries with scarcity of deceased donors.

LDLT was initially performed in the 1990s for small or pediatric patients with end-stage liver disease. Procedures using the left lobe or lateral segment were performed at the University of Chicago.¹⁸ Although these techniques were attempted in adult recipients, the smaller left hepatic lobe provided insufficient hepatic mass for most adult patients. The first adult-to-adult right hepatic lobe transplantation was reported in 1993 by Yamaoka and colleagues.¹⁹ The first successful donor right hepatic lobe transplantation was performed in the United States in 1997.²⁰

Other than increasing the pool of potential donors, LDLT has some other advantages. Patients can undergo timely transplantation without waiting for a deceased donor organ. This

Figure 92-4 Diagram shows surgical anatomy of OLT by standard end-to-end IVC anastomotic technique. End-to-end anastomosis between the donor and recipient inferior vena cava (IVC) is performed cranial and caudal to the liver. A choledochojejunal anastomosis is also demonstrated. CBD, common bile duct; H.A., hepatic arterial; P.V., portal venous.

may confer survival benefit to LDLT, which has been shown to be higher compared with deceased donor transplantation.²¹ A detailed preoperative assessment and clinical management of often critically ill potential recipients are possible. Finally, living donor grafts are obtained from healthy donors who have been extensively screened for disease. Despite these advantages, there are unique risks of LDLT. The risk of donor death is 1.7 per 1000 in the United States.²² Clavien grade 3 or 4 complications are seen in 2.8% of the donors.²²

IMAGING EVALUATION OF THE POTENTIAL LIVING RELATED LIVER DONOR

The ideal screening modality for potential living liver donors would accurately evaluate hepatic parenchyma, provide data for split liver volume assessment, and depict intrahepatic and extrahepatic vascular anatomy before potential partial hepatectomy.²³ MRI is used to depict the vascular variants, hepatic volume issues, and fatty infiltration that may preclude right hepatic lobe donation. Conventional or hepatocyte-specific contrast agent-enhanced MRI can be performed to demonstrate problems with biliary anatomy.²⁴⁻²⁷ Hepatocyte- and biliary-specific contrast agents (e.g., gadobenate dimeglumine, gadoxetate disodium [Gd-EOB-DTPA], mangafodipir trisodium) not only allow dynamic contrast-enhanced scanning but also are differentially taken up by functioning hepatocytes and excreted into the biliary tree. This allows excellent delineation of the biliary anatomy.²⁸

The exquisite spatial resolution of multidetector CT has made it the most widely used modality for the preoperative evaluation of living donors.^{24,29} Rapid scanning makes bolus

timing even more critical; either test boluses or automated triggering is crucial for obtaining images during peak hepatic arterial enhancement. The 2.5-mm collimated images are then obtained during a portal venous (“hepatic”) phase so that portal and hepatic venous anatomy may be displayed. Both the source and reconstructed images should be meticulously reviewed. Volume rendered images are helpful for displaying global anatomy, but many radiologists rely heavily on sliding thick-slab maximum intensity images.

PARENCHYMAL ASSESSMENT

The size of the potential right lobe graft is a crucial determinant of graft viability. A sufficiently large right lobe is needed to prevent the “small for size” syndrome; transplantation of insufficient hepatic mass may result in poor allograft function, graft failure, or the death of the recipient.³⁰ Small grafts are also more prone to sinusoidal injury from increased portal pressures.³¹ Several approaches to assessment of sufficient liver volume for transplantation have been applied; graft weight/recipient standard liver volumes of less than 40% or graft-to-recipient weight ratios of less than 85% are associated with poor outcomes.^{30,32} Both MRI and CT can be used to accurately calculate split liver volumetric measurements of potential donors.

Unenhanced CT or in-phase/out-of-phase MRI is also used to detect fatty infiltration in the potential donor graft.²³ It has been well shown that steatosis increases the likelihood of graft dysfunction and reduces hepatic regenerative function.³³⁻³⁵ Several centers still routinely perform liver donor biopsies to better quantify steatosis.

VASCULAR ASSESSMENT

Anatomic variations of extrahepatic vascular anatomy (e.g., replaced left or right hepatic arteries) are common, well known, and easily demonstrated by CT angiography. The unique contribution of multidetector CT to the evaluation of the prospective right liver donor is its ability to detect variations in arterial and venous anatomy that may traverse the hepatectomy plane.^{36,37} Although adequate hepatic mass may be procured with several techniques (left donor hepatectomy, extended right donor hepatectomy), a traditional right hepatectomy along Cantlie's line, a relatively avascular plane immediately lateral to the middle hepatic vein, is preferred in most institutions. Parenchymal dissection to the hilar plate is performed by ultrasonic dissection. Accurate definition of vascular structures traversing this plane is needed to prevent inadvertent vessel injury and ischemic injury to either the graft or remaining donor liver.

Traditional hepatic arterial anatomy, in which the proper hepatic artery branches into right and left hepatic branches, is seen in only 55% of patients. Although many variants are easily shown at CT, a crucial consideration for donor graft retrieval is the blood supply to segment IV. A middle hepatic artery branch that arises from the right hepatic artery will be disrupted during donor hepatectomy. Inadvertent ligation of this branch during graft retrieval may cause biliary ischemic damage to the remaining donor medial segment. Other significant vascular variants that may affect donor selection include a short right hepatic artery, trifurcation of the common hepatic artery into the gastroduodenal artery and right and left hepatic arteries, and origination of the right or left hepatic arteries before the gastroduodenal artery. Replaced hepatic arteries in the recipient are not absolute contraindications to transplantation, although arterial reconstructions can be more technically demanding. Finally, recipient celiac artery stenosis from atherosclerotic disease or a median arcuate ligament may predispose to graft infarction and biliary complications.²³ Sliding thick-slab maximum intensity projection images obtained from a second portal venous (hepatic) phase are used to display potentially significant hepatic venous variants. Variations in branching of the middle hepatic vein are particularly important because they may necessitate an altered hepatectomy plane. For example, inadvertent ligation of a prominent early branch (>3 mm) of the middle hepatic vein draining segment VIII may result in

segmental hepatic venous congestion in the transplanted liver (Fig. 92-5). The early branch may be spared with a more lateral hepatectomy plane (although this may decrease the volume of the graft), or the surgeon may maintain outflow drainage to segment VIII by directly anastomosing the branch to the recipient IVC. Inferior accessory right hepatic veins are also common variants that may have an impact on graft retrieval; most transplant surgeons will try to preserve inferior accessory veins larger than 3 to 5 mm. If the distance between the vein and the hepatic venous confluence is less than 4 cm, it may be possible to implant both the main and accessory right veins with a single partially occluding clamp on the IVC.²³

Variations in portal venous anatomy also need to be considered before right hepatic lobe donation. Early right portal vein bifurcation or main portal vein trifurcation may make transplantation difficult. The portal vein may be reconstructed on the back table, and vein or interposition grafts may be employed, but this increases the risk of portal vein thrombosis (Fig. 92-6). Portal venous flow to segment IV should also be carefully delineated; flow to the medial segment can arise from either the right or left portal vein; inadvertent disruption of portal venous inflow during donor hepatectomy may result in remaining donor liver ischemic injury. Flow to the entire left lobe through a branch from the right portal vein is an absolute contraindication to organ donation.²³

BILIARY ASSESSMENT

Postoperative biliary leaks and strictures are the most common complication after LDLT. MRI is used to identify aberrant biliary anatomy as inadvertent transection of biliary radicals increases the risk of biliary leak.³⁸ Drainage of the right posterior bile duct into the left hepatic duct and biliary trifurcation are common variants that can lead to bile duct injury in the donor.²⁴

Postoperative Complications

HEPATIC ARTERIAL COMPLICATIONS

Hepatic artery complications include stenosis, thrombosis, pseudoaneurysm, and arteriovenous fistula formation. Arterial complications place the patient at risk for biliary ischemia as

Figure 92-5 Preoperative evaluation of the potential living liver donor. **A.** Thick-slab axial maximum intensity projection CT image shows drainage of segment VIII by a prominent early branch of the middle hepatic vein (arrows). **B.** Enhanced CT shows segmental hepatic venous congestion of the transplanted liver (arrowheads).

Figure 92-6 CT evaluation of the potential living liver donor. Coronal thick-slab maximum intensity projection CT image shows portal venous trifurcation (arrow).

the bile ducts in the transplanted liver receive blood supply only from the hepatic arteries.³⁹ Biliary ischemia results in strictures, abscesses, sepsis, allograft failure, and death.⁴⁰

Normal Postoperative Hepatic Arterial Doppler Findings

After transplantation, hepatic arterial assessment is routinely performed with color and spectral Doppler ultrasound. A baseline study is usually obtained within the first 24 hours after transplantation; additional follow-up imaging is dictated by the patient's clinical course.⁴¹ Careful inspection should assess for any arterial narrowing or focal dilation. Color and spectral Doppler evaluation documents appropriate flow direction and waveform appearance.⁴² The normal main hepatic artery has continuous antegrade flow with a rapid upstroke and resistive index (RI) of 0.55 to 0.8^{39,42-45} (Fig. 92-7). The right and left hepatic arteries should have a similar appearance.⁴²

In the first 72 hours after transplantation, arterial peak systolic velocity and RI may be variable. Median peak systolic velocity is 103 cm/s; however, values range from 13 to 367 cm/s in the first 48 hours.⁴⁶ Early elevated peak systolic velocity with normal RI and waveforms may be due to postoperative edema, variations in the arterial internal diameter, or vessel redundancy.⁴⁶ Gray-scale ultrasound can be used to identify kinks due to vascular redundancy causing spuriously elevated velocities and help differentiate them from stenosis. Adjustment of the Doppler interrogation angle is necessary to accurately measure the velocity at such sites.

High-resistance flow (RI > 0.8, absent or reversed diastolic flow) can be seen in the first 72 hours in almost half the patients and usually returns to normal within 7 to 15 days.⁴⁷ This transient elevation has not been associated with any clinical deterioration or shortened survival time and may be due to postoperative allograft edema or vessel spasm.^{48,49} Low-resistance flow is a good indicator of hepatic arterial complications but can be a normal transient finding in the immediate postoperative period, probably due to anastomotic edema.

Figure 92-7 Normal main hepatic arterial waveform in a transplant liver with rapid systolic upstroke and normal diastolic flow (RI, 0.67; normal range, 0.55-0.8).

Transient postoperative findings will resolve on follow-up studies, whereas findings due to arterial complications will persist or deteriorate.⁵⁰

Hepatic Artery Thrombosis

Hepatic artery thrombosis (HAT) is the most common vascular complication after liver transplantation with mortality rates of 20% to 60%.^{39,40,51} Occurrence varies in the literature from 3% to 6% in adults,⁵²⁻⁵⁵ with reported occurrence in the pediatric population as high as 12%.^{51,52} Risk of HAT is associated with surgical technique, including arterial conduits, prolonged operation time, variant hepatic arterial anatomy, and retransplantation.^{53,56} The high mortality rate and resultant complications of HAT have led to routine surveillance with ultrasound in the early postoperative period to assess for thrombus.⁴¹

HAT can be divided into early and late categories; early HAT occurs within the first 15 to 30 days after transplantation.^{39,56} Complications of early HAT include fulminant necrosis, liver abscess, sepsis, and graft failure.⁵³ Patients present with massive hepatic necrosis and rapid clinical deterioration, delayed biliary leak and bilomas, or relapsing bacteremia^{51,52} (Fig. 92-8). Development of HAT more than 1 month after transplantation may have a less fulminant course and more variable presenting symptoms.^{57,58}

Ultrasound is diagnostic in up to 92% of cases⁵⁹ by showing absent flow in the main hepatic artery. In some cases of late HAT, development of collaterals can cause tardus-parvus waveforms in the intrahepatic right and left branches.⁵⁸ In general, demonstration of tardus-parvus waveform in the hepatic arteries should raise concern for upstream HAT or hepatic artery stenosis (Fig. 92-9). Causes of false-positive Doppler ultrasound diagnosis of HAT include severe hepatic edema, hypotension, and hepatic artery stenosis.⁶⁰ Evaluation of the main hepatic artery with ultrasound may be limited by body habitus, overlying bowel gas, or bandages, limiting sonographic windows. Confirmation with CT angiography or digital subtraction angiography (DSA) should be considered in any suspicious case (Fig. 92-10).

Figure 92-8 Hepatic necrosis after hepatic artery thrombosis. Ischemia has caused biliary and hepatic necrosis in the left hepatic lobe with formation of a large biloma (arrows).

Figure 92-10 Hepatic artery thrombosis. CT angiogram of a patient after OLT shows occlusion of the main hepatic artery (arrow).

Figure 92-9 Hepatic artery thrombosis. Tardus-parvus waveform (delayed upstroke and decreased RI) in an intrahepatic collateral vessel after hepatic arterial thrombosis.

Treatment of HAT requires retransplantation in up to 75% of cases, often emergent because of massive necrosis.^{51,61,62} Percutaneous or surgical thrombectomy can be considered, particularly in cases with early diagnosis. Early endovascular or surgical revascularization can lead to graft salvage or serve as a bridge to retransplantation.^{63,64}

Hepatic Artery Stenosis

Hepatic artery stenosis (HAS) occurs less often than HAT.^{51,65,66} It is more common at the anastomosis⁴³ but may occur within the graft artery. HAS can lead to complications similar to those of HAT but often has a more insidious course, with symptoms developing during days to weeks. Patients may present with abnormal serum liver enzymes or biliary complications such as nonanastomotic strictures, which occur in up to 22%.⁶⁵ HAS may also be detected without symptoms during routine Doppler ultrasound screening.⁶⁵

As with HAT, color and spectral Doppler ultrasound is the most common screening test for HAS. Direct findings of HAS include turbulent flow and elevated peak systolic velocity of more than 2 m/s in the main hepatic artery at the site of the stenosis⁴³ (Fig. 92-11A). However, the site of stenosis may not be directly visualized, and secondary Doppler findings downstream from the stenosis are useful in diagnosis of HAS. Secondary findings are due to decreased arterial resistance distal to the stenosis and include increased diastolic flow (RI < 0.55) and delayed systolic upstroke (systolic acceleration time > 0.08), with sensitivity and specificity ranges of 73% to 83% and 60% to 73%^{43,45} (Fig. 92-11B). A tardus-parvus waveform may be seen distal to the anastomosis. False positives can occur as RI may be low in the first 72 hours after transplantation.⁴³ The transient postoperative Doppler findings should resolve in a few days, whereas changes due to arterial stenosis or thrombosis will persist or deteriorate. Deterioration of a previously documented normal hepatic arterial waveform in the postoperative period is concerning for arterial complication (HAT or HAS). CT angiography or DSA can confirm findings (Fig. 92-11C, D). DSA allows therapeutic interventions to be performed at the time of diagnosis.

Treatment of HAS includes percutaneous transarterial angioplasty or stent placement, surgical revision with various arterial or venous graft reconstructions, and retransplantation. Patients with biliary complications require retransplantation more often than those without do.⁶⁵ Surgical revision was more common in the earlier literature,⁶⁵ but management with percutaneous angioplasty without or with stent placement is frequently performed with high success rates⁶⁷ and survival rates similar to those of surgical reconstruction⁶⁸ (Fig. 92-11E). Untreated or recurrent HAS after intervention can progress to HAT, and patients with HAS are more likely to develop biliary complications even with HAS treatment.^{51,65-68}

Hepatic Arterial Pseudoaneurysm

Hepatic artery contained rupture or pseudoaneurysm is a rare arterial complication (Fig. 92-12). Pseudoaneurysm can occur at the arterial anastomotic site as a result of infection or be

Figure 92-11 Hepatic artery stenosis.

A. Doppler ultrasound image of the main hepatic artery shows turbulence and increased peak systolic velocity (365 cm/s) consistent with focal stenosis. **B.** Distal to the stenosis, the main hepatic artery shows increased diastolic flow (RI, 0.44) with normal velocity. **C.** CT angiogram shows focal narrowing of the main hepatic artery (arrow). **D.** DSA confirms the main hepatic artery stenosis (arrow). **E.** DSA image obtained after placement of a stent across the stenotic segment. The previously stenotic segment now appears patent (arrow).

related to hepatic artery angioplasty procedures. Pseudoaneurysm may be found within the hepatic parenchymal arterial branches as a complication of intervention, such as biopsy or biliary drainage.^{69,70} Pseudoaneurysm rupture can be manifested with gastrointestinal bleeding from hemobilia or hemo-peritoneum and shock.

Ultrasound examination shows a cystic structure along the course of the hepatic artery or within the hepatic parenchyma. With color Doppler assessment, there is disorganized color flow filling the structure.³⁹ Contrast-enhanced CT or MRI can also aid in diagnosis. The pseudoaneurysm will follow blood pool on multiphasic examination, with avid arterial phase enhancement that washes out similar to aortic intensity on later phases.^{40,71} Treatment of hepatic artery pseudoaneurysm depends on location and severity of clinical symptoms. Surgical management with resection is the routine treatment, particularly in mycotic pseudoaneurysm because endovascular material may serve as an infectious nidus. Intravascular hepatic

artery occlusion may serve as a temporizing measure to stabilize patients with active bleeding before surgery. Extrahepatic pseudoaneurysm may be excluded with stent placement across the location, although long-term patency of these stents in small arteries is unknown. Intrahepatic pseudoaneurysm can be treated with coil embolization.^{40,71}

PORTAL VENOUS COMPLICATIONS

Normal Postoperative Portal Venous Doppler Findings

The normal post-transplantation portal vein has smooth walls and an anechoic lumen with mild anastomotic narrowing up to 0.5 cm, probably of no significance in the absence of clinical abnormalities. The anastomosis may be visible as an echogenic shelllike ring in the portal vein wall (Fig. 92-13). Doppler analysis shows continuous forward flow toward the liver with mild respiratory variation. Flow velocity in the main portal vein is

Figure 92-12 Hepatic artery pseudoaneurysm. **A.** Celiac arteriogram demonstrates a hepatic arterial pseudoaneurysm (arrow) that was surgically repaired. **B.** Another patient with a ruptured hepatic arterial pseudoaneurysm. Note the large left subhepatic space hematoma. The pseudoaneurysm (arrow) is depicted as a focally enhanced enlargement of the artery.

Figure 92-13 Normal ultrasound appearance of the main portal vein after OLT. An indentation is noted at the anastomotic site (arrow).

variable, with velocities decreasing over time after transplantation on serial examinations.³⁹

Portal Venous Stenosis and Thrombosis

Portal vein complications include stenosis and thrombosis. They occur in 1% to 2% of transplant patients, particularly in the pediatric and living related donor population because of small or short graft vein size.^{51,55,64} Causes include misalignment or size discrepancy between the donor and recipient, hypercoagulable state of the recipient, thrombus from portal venous bypass catheter, or prior portal vein surgery.⁵¹ Patients present with signs of portal hypertension or hepatic failure. Portal vein stenosis is seen at ultrasound examination with narrowing at the anastomosis and color aliasing. Velocity in the stenotic area is three to four times greater than velocity upstream from the stenosis^{72,73} (Fig. 92-14).

Treatment options for portal vein stenosis include percutaneous thrombolysis, angioplasty or stent placement, and surgical thrombectomy or stenosis with anastomotic revision or

venous jump graft.^{39,51} Percutaneous balloon angioplasty is performed through a peripheral portal vein branch. The right portal vein is preferred because of its straight course. The stenosis is treated with balloon angioplasty until the pressure gradient is less than 5 mm Hg. Patients with persistent pressure gradient after angioplasty or recurrent stenosis after treatment are usually treated with stent placement. Balloon angioplasty has 50% patency at 6 months, with stent patency of 100% in 47 months.⁷⁴

Portal vein thrombus is seen at ultrasound examination as hypoechoic or heterogeneous thrombus within the vessel and little or no color or power Doppler flow³⁹ (Fig. 92-15). Treatment of acute portal vein thrombus includes thrombolysis, thrombectomy, anastomotic revision, and retransplantation.⁷⁵

HEPATIC VEIN AND INFERIOR VENA CAVA COMPLICATIONS

IVC and hepatic vein complications of OLT are rare, occurring in less than 1% to 2% of transplants, and generally are due to stenosis or thrombosis.^{51,76} Knowledge of the type of venous reconstruction is often critical for imaging interpretation as IVC and hepatic vein stenosis and thrombosis typically occur near the anastomosis.⁷² End-to-end caval reconstruction produces suprahepatic and infrahepatic anastomoses, each of which should be evaluated for stenosis. The piggyback technique joins the donor IVC with the recipient's hepatic vein confluence while maintaining a blind-ended stump of the donor's retrohepatic IVC (Fig. 92-16).

Normal hepatic veins and IVC have triphasic spectral waveform due to transmitted cardiac pulsation (Fig. 92-17). In patients with IVC stenosis, the cardiac pulsations are not transmitted to the hepatic veins, which results in monophasic waveforms within the hepatic veins, IVC, or both^{76,77} (Fig. 92-18). Of note, in the postoperative period, it is not uncommon to see abnormal monophasic waveforms or turbulence within the hepatic veins or IVC. This is often secondary to anastomotic edema or compression from hematoma or fluid and should resolve over time.⁵⁰ The IVC anastomosis may be focally narrowed, and color aliasing from increased turbulent flow may be visualized (Fig. 92-19). A threefold or fourfold velocity gradient with the prestenotic segment can be seen in IVC stenosis.⁴⁰ Hepatic vein stenosis is more common in living donor transplants, and sixfold increases in velocity have been reported.⁷⁶

Figure 92-16 Piggyback IVC anastomosis. Sagittal ultrasound image shows ligated donor infrahepatic IVC (arrowhead) and recipient IVC (arrow).

Figure 92-17 Normal hepatic venous waveform. Normal triphasic hepatic venous waveform with a peak above the baseline representing flow away from the heart and two peaks below the baseline indicating flow toward the heart.

Remembering that IVC and hepatic vein complications are rare, abnormal ultrasound findings should always be correlated with the patient's clinical presentation. Clinical presentation varies on the basis of the location and severity of obstruction, but symptoms include hepatomegaly, ascites, pleural effusions, and edema.⁷⁸ In clinically suspected cases, multiplanar CT or MRI may demonstrate focal IVC or anastomotic narrowing, hepatic vein enlargement, and abnormal liver perfusion typical of Budd-Chiari syndrome or hepatic congestion.⁴⁰ Venography is the "gold standard" but is invasive and usually reserved for cases in which there is a high index of suspicion. Angioplasty and expandable stents have proved useful to treat IVC and hepatic vein stenosis.^{40,79}

IVC or hepatic vein thrombosis may have imaging findings similar to those of stenosis. Echogenic intraluminal filling defects and decreased color Doppler flow are demonstrated on

Figure 92-18 Monophasic hepatic venous waveform. Monophasic hepatic venous waveform is seen in patients with hepatic venous outflow obstruction but is nonspecific and can be present without obstruction.

ultrasound⁴⁰ (Fig. 92-20). Multiplanar contrast-enhanced CT or MRI can usually better illustrate the extent of thrombus. An important thing to know is that thrombus normally develops in the piggyback retrohepatic IVC stump, and this finding should not be misdiagnosed as IVC thrombosis.⁸⁰

BILIARY COMPLICATIONS

Biliary complications are a significant cause of morbidity and mortality in OLT.⁸¹ However, with better patient and organ selection and improvement in immunosuppression and surgical techniques, the incidence of these complications has significantly decreased. Nevertheless, biliary complications are still seen in 5% to 25% of patients.⁸² Most occur early, typically within the first 3 months.^{39,78} However, exceptions include stones and strictures, which may develop months to years after transplantation.⁸⁰ In general, biliary complications can be classified as due to obstruction or leak.

Normal Postoperative Cholangiography Findings

In patients with end-to-end choledochocholedochostomy, the donor and recipient ducts should be smooth and uniform in caliber. Mild smooth anastomotic narrowing is common and usually insignificant in asymptomatic patients. On occasion, size discrepancies can exist between the respective ducts, mimicking anastomotic obstruction or stenosis.⁸³ Residual cystic ducts may be present in the donor or recipient system, or both, and should not be confused with leaks. If a T tube is used, it is typically inserted in the recipient duct, more than 5 mm distal to the anastomosis to minimize the risk of ischemia, with the proximal limb bridging the anastomosis. Direct cholangiography should show no extravasation with drainage of contrast material distally into duodenum (Fig. 92-21).

Biliary Obstruction

Biliary obstruction is most often secondary to stricture formation and may be classified as anastomotic or nonanastomotic.

Figure 92-19 Suprahepatic caval stenosis. **A.** Color Doppler image shows focal aliasing at piggyback anastomosis. Hepatic venous flow (not shown) was monophasic. **B.** Venacavography in another patient shows significant narrowing at the suprahepatic caval anastomosis (arrow). This was successfully treated with balloon angioplasty.

Figure 92-20 IVC thrombosis. Gray-scale ultrasound image shows nonocclusive echogenic caval thrombus (arrow) adjacent to the caudal IVC anastomosis (arrowheads) in a patient who had end-to-end IVC anastomosis.

Figure 92-21 Normal postoperative T-tube cholangiogram. T-tube insertion is a few millimeters distal to the anastomosis in the recipient duct (arrowhead). Injected contrast material outlines the biliary tree without any narrowing or filling defect and flows into the duodenum without obstruction. Both donor and recipient cystic duct stumps are present in this patient (arrows). This should not be confused with a leak.

The incidence of biliary stricture is 12% for deceased donors and 19% for living donors.¹⁵ OLT patients with biliary obstruction present clinically with signs of graft dysfunction and abnormal biliary enzymes (total bilirubin, alkaline phosphatase). However, clinical findings are often ambiguous and can be confused with rejection, and imaging is often necessary for diagnosis.⁸³ In postoperative patients with a T tube, direct cholangiography through the existing T tube is the preferred method of evaluating the biliary system. Magnetic resonance cholangiopancreatography and ultrasound can be used in patients without a T tube or who have a biliary-enteric anastomosis.

Anastomotic Biliary Stricture

Anastomotic strictures are due to the surgical technique or fibrosis at the anastomotic site.⁸⁴ Although most anastomotic strictures are manifested within the first 3 months, they can become evident years after transplantation.^{85,86}

Clinically significant anastomotic stenosis is usually characterized by smooth proximal biliary ductal dilation to the

level of the anastomosis (Fig. 92-22). With contrast cholangiography, filling defects corresponding to biliary debris, sludge, or stones may be seen proximal to the stenosis. Ultrasound shows proximal biliary ductal dilation and echogenic debris or stones. Ultrasound is not as reliable as MR cholangiography, which appears more sensitive at detecting biliary complications, including stenosis.⁸⁷⁻⁸⁹ Nevertheless, ultrasound or MR cholangiography may be inconclusive, demonstrating no significant biliary dilation or abnormality, even in patients with clinically significant obstruction. Therefore, when no T tube is present, direct cholangiography with endoscopic retrograde

Figure 92-22 Biliary anastomotic stricture. Endoscopic retrograde cholangiopancreatography image shows a tight biliary anastomotic stricture (arrow). Endoscopic stenting was performed.

cholangiopancreatography or percutaneous transhepatic cholangiography may be required for diagnosis and can facilitate treatment with balloon angioplasty or stenting. On occasion, surgical revision, usually to a choledochojejunostomy, must be performed.⁸⁶

Nonanastomotic Strictures

Compared with anastomotic strictures, nonanastomotic strictures are more menacing because of their high association with biliary ischemia. Acceptance of older donors, donors with cardiac death, and donors with extended criteria has resulted in an increase in incidence of nonanastomotic strictures.^{90,91} Patients with bilioenteric reconstruction or history of primary sclerosing cholangitis are also prone to development of nonanastomotic strictures.⁷¹

Nonanastomotic biliary strictures are manifested clinically as cholestasis or episodes of cholangitis. About half the cases present within the first year; the rest gradually present during several years after transplantation.⁹² The strictures are typically hilar but can be intrahepatic and involve multiple sites. Intrahepatic peripheral biliary involvement is more common with late presentation of nonanastomotic stricture.⁹² Nonanastomotic strictures are often due to biliary ischemia or necrosis caused by hepatic arterial thrombosis or stenosis (macroangiopathic form). A microangiopathic form is due to injury to peribiliary vascular plexus by ischemia-reperfusion or immunologic injury.⁹¹ Recurrent primary sclerosing cholangitis can also cause nonanastomotic strictures.

In patients with nonanastomotic strictures, direct cholangiography demonstrates irregular narrowing or obstruction with focal areas of biliary dilation (Fig. 92-23). There may be focal collections of contrast material pooling within the liver parenchyma, consistent with bilomas. Filling defects due to stone or debris may be present. MRI can show biliary

Figure 92-23 Biliary nonanastomotic stricture. Endoscopic retrograde cholangiopancreatography image shows an irregular hilar stricture (arrow). Multiple filling defects are present in the proximal dilated biliary radicals (arrowheads), representing debris.

Figure 92-24 Biliary nonanastomotic stricture. Delayed hepatocyte phase MRI with use of hepatobiliary contrast agent (Gd-EOB-DTPA). Excreted contrast material in the biliary duct shows an ischemic biliary hilar stricture (arrow).

dilation and sloughed mucosal casts within the biliary tree, but normal-appearing ducts are not uncommon in the acute setting (Fig. 92-24).

Color Doppler ultrasound should be used to exclude ischemia in all patients with nonanastomotic strictures. Biliary ischemia can be manifested as a spectrum of findings reflecting the location and severity of vascular compromise. Arterial stenosis can result in fibrotic strictures or obstructing casts of sloughed mucosa or sludge. Alternatively, severe ischemia or infarction

Figure 92-25 Biliary anastomotic leak. Cholangiography through an existing T tube shows biliary leak at the anastomosis (arrow).

can result in biliary necrosis, obstruction, or leak. Careful sonographic interrogation of the hepatic artery and its branches should be performed, although contrast-enhanced CT or MRI is occasionally required. Typically, hepatic arterial abnormalities precede biliary abnormalities by 1 to 3 weeks. Because biliary dilation is minimal in the early stages of stricture formation, sonography is inadequate to examine the intrahepatic bile ducts.⁹³

Ischemic strictures may temporarily respond to balloon angioplasty or stenting, but repeated intervention is usually necessary.⁹⁴ Ultimately, surgical revision or retransplantation is required in many cases.

Biliary Leak

The incidence of biliary leak is about 7.8% for deceased donors and 9.5% for living donors.¹⁵ Biliary leaks are manifested either in the first month after OLT or later immediately after removal of the T tube.⁹¹ The common locations of biliary leak after OLT are the biliary anastomosis (Fig. 92-25), the cystic duct stump (Fig. 92-26), and the T-tube insertion site. Leaks can also occur along the resection margin in partial living donor transplants. Because biliary ischemia may lead to necrosis and leak, non-anastomotic leaks should raise concern for hepatic arterial injury and indicate emergent sonographic evaluation. Most bile leaks are managed by biliary stenting.^{95,96} Small leaks may close spontaneously. Repeated surgery may be required for large leaks. Large leaks can be a significant cause of morbidity or death owing to increased risk of infection in immunocompromised patients, and large bilomas associated with biliary leaks have to be drained.

REJECTION

Hepatic allograft rejection is the most common cause of late allograft failure. Acute cellular rejection usually occurs in the first 2 weeks after transplantation and affects 50% to 100% of the allografts.⁹⁷ It is usually treated by added immunosuppression. Chronic ductopenic rejection occurs in about 8% of the patients and is manifested 6 weeks to 6 months after transplantation.⁹⁷ Ductopenic rejection causes a spectrum of abnormalities ranging from mild loss of bile ducts and mild

Figure 92-26 Cystic duct stump leak. Cholangiography through an existing T tube shows biliary leak (arrow) at the cystic duct stump (arrowheads).

cholestasis, which is potentially reversible, to a severe form in which most interlobular and septal bile ducts are lost, resulting in severe cholestasis that is unresponsive to therapy. Severe ductopenic rejection is often associated with an arteriopathy of medium-sized hepatic artery branches.

The role of imaging in patients with rejection is largely to exclude other vascular or biliary causes of graft dysfunction. Imaging is neither sensitive nor specific for detection of rejection. The diagnosis of rejection is established by histopathologic evaluation after liver biopsy. Cholangiography may show variable degrees of poor filling, narrowing, or stretching of the bile ducts. Arteriography may show varying degrees of narrowing, stretching, or slow flow in intrahepatic arteries.⁹⁸ Loss of hepatic

artery diastolic flow on Doppler examination is neither a specific nor sensitive finding of allograft rejection.⁴⁸

FLUID COLLECTIONS

Hematomas, seromas, and bilomas are common postoperative fluid collections. Hematomas are identified by their high attenuation on CT. Hematomas change in character over time and become low attenuation. Most collections do not cause any symptoms and resolve spontaneously. Development of wall enhancement or gas in a fluid collection suggests infection. Infected collections and bilomas need to be drained. This can be done percutaneously with imaging guidance.

POST-TRANSPLANTATION MALIGNANT DISEASE

Solid organ transplant recipients are at a higher risk for development of malignant disease. Long-term exposure to immunosuppressive agents and increased risk of oncogenic viral infection are probable causes. Nonmelanoma skin cancer, post-transplantation lymphoproliferative disorder (PTLD), Kaposi's sarcoma, and anogenital tumors are the most common post-transplantation tumors.

PTLD is a cause of morbidity and mortality in post-transplantation patients. It represents a spectrum of diseases ranging from indolent polyclonal proliferation to aggressive lymphoma. Infection by Epstein-Barr virus (EBV) in an immunosuppressed host induces diffuse polyclonal B-lymphocyte proliferation, which results in PTLD. The risk factors include recipient EBV seronegativity, younger recipient age, older donors, high levels of immunosuppression, and antilymphocyte therapies.⁹⁹ EBV infection-associated PTLD occurs in the first 1 to 2 years after liver transplantation, whereas non-EBV-related PTLD occurs later.

PTLD occurs more frequently in the pediatric transplant population because of the higher likelihood of pretransplantation EBV seronegativity. The changes in immunosuppression regimens with lower levels of tacrolimus and cyclosporine and less steroid use has decreased the incidence of PTLD.⁹⁹ Recent data indicate that the incidence of PTLD is now 1.7% for pediatric liver transplants, which is lower than in earlier reports.⁹⁹

Virtually any body tissue can be involved, but the abdominal cavity is the most common site of PTLD. Extranodal disease

(80%) is more common than nodal disease (20%) in the abdominal cavity.¹⁰⁰ The gastrointestinal tract and liver are most often involved in the abdomen. The distal small bowel and proximal colon are the most common sites in the gastrointestinal tract.^{100,101} On imaging, bowel involvement can be manifested with wall thickening, eccentric mass, or luminal ulceration. Liver involvement can be in the form of low-attenuation hypovascular nodules, diffuse infiltration, or porta hepatis mass.¹⁰⁰⁻¹⁰² Splenomegaly or diffuse low-attenuation nodules (less common) can be manifested with splenic involvement.¹⁰⁰⁻¹⁰² Opportunistic infections can have a similar appearance in solid organs and need to be considered in the differential diagnosis. CT/PET is a useful imaging examination for the detection of multifocal PTLD and for assessment of responses to therapy (Fig. 92-27).

PTLD is initially treated with reduction in immunosuppression. Chemotherapy and rituximab (a monoclonal antibody) are used in unresponsive cases.¹⁰³ The mortality of PTLD is high despite treatment.

Patients undergoing liver transplantation for HCC are at risk for recurrence related to initial tumor stage. Poor prognostic indicators for recurrent HCC include vascular invasion, spread to extrahepatic lymph nodes, bilobar tumor, and size larger than 3 cm. Patients undergoing liver transplantation with an incidentally detected HCC found at sectioning of the explant have a low incidence of recurrence. In patients undergoing liver transplantation for HCC, recurrent tumor most commonly involves the lungs, allograft, local and distant lymph nodes, adrenal gland, and bone.¹⁰⁴ Patients with cholangiocarcinoma also have a high recurrence rate after transplantation, and cholangiocarcinoma is considered a contraindication to liver transplantation.¹⁰⁵

Summary

Liver transplantation has become the standard treatment of many patients with end-stage liver disease. Long-term patient and graft survival has continued to improve as a result of improved surgical techniques and improved immunosuppressive therapy. Radiologic imaging has an important role in proper patient selection and providing information that may alter the surgical technique. Most important, early radiologic recognition and treatment of postoperative complications are necessary to lower postoperative morbidity and mortality.

Figure 92-27 Post-transplantation lymphoproliferative disease. A. CT shows focal thickening of proximal jejunum 3 years after transplantation (arrow). The patient presented with melena. **B.** CT/PET shows that the segment is markedly FDG avid (arrow).

93-2

Hepatomegaly in the Neonate

Nutritional disorder Heart failure Infection Biliary atresia Metabolic defect Primary neoplasm Metastases

TABLE
93-3

Focal Hepatic Enlargement

COMMON Anomalous lobes (Riedel) Metastasis Cirrhosis Regenerative nodules or lobes Hemangioma Cysts Adenoma Focal nodular hyperplasia Hepatoma Lymphoma Cholangiocarcinoma
UNCOMMON Hemangioendothelioma Actinomycosis Abscess (fungal or pyogenic) Biliary cystadenoma Hamartoma Hepatoblastoma Sarcoma Spindle cell neoplasm Teratoma Cholangioma

TABLE
93-4**Liver Atrophy with Compensatory Hypertrophy**

Cirrhosis
 Hepatic vein obstruction (segmental)
 Portal vein obstruction (segmental)
 Intrahepatic biliary obstruction (segmental)
 Budd-Chiari syndrome
 Radiation therapy
 After chemotherapy for hepatic tumor
 Surgical resection
 Liver metastases
 Lobar agenesis

TABLE
93-7**Neonatal Liver Calcification**

Calcified venous thrombi (e.g., after umbilical vein catheterization)
 Hematoma
 Cytomegalovirus infection
 Herpesvirus infection
 Toxoplasmosis
 Abscess
 Biliary calcification
 Hemangioma
 Hamartoma
 Hepatoblastoma
 Hepatocellular carcinoma
 Metastatic neuroblastoma
 Ischemic infarct
 Rubella

TABLE
93-5**Hepatic Capsular Retraction****ADJACENT TO A HEPATIC TUMOR**

Primary malignant tumors
 Hepatocellular carcinoma
 Fibrolamellar hepatocellular carcinoma
 Intrahepatic cholangiocarcinoma
 Epithelioid hemangioendothelioma
 Metastatic tumors
 Adenocarcinoma of the colon, stomach, breast, lung, pancreas, and gallbladder
 Postembolization of hepatocellular carcinoma
 Postchemotherapy of malignant tumors
 Benign tumor
 Hemangioma

WITHOUT AN ADJACENT HEPATIC TUMOR

Confluent hepatic fibrosis
 Oriental cholangiohepatitis
 Bile duct necrosis
 Pseudoretraction
 Accessory fissure
 Normal liver parenchyma between the protruded masses

TABLE
93-8**Portal Venous Gas**

Mesenteric infarction
 Air intravasation during double-contrast barium enema
 Acute gastric dilation
 Percutaneous abscess drainage
 Necrotizing enterocolitis
 Umbilical vein catheterization
 Erythroblastosis fetalis
 Diverticulitis
 Inflammatory bowel disease
 Corrosive ingestion
 Diabetic coma
 Hemorrhagic pancreatitis
 Hydrogen peroxide enema
 Emphysematous cholecystitis
 Mechanical bowel obstruction with ischemia
 Necrotic colon cancer
 Perforation of gastric ulcer into mesenteric vein
 Abscess
 Closed-loop obstruction
 Pseudomembranous colitis
 Gastric emphysema
 Toxic megacolon
 Sepsis
 Corrosive gastritis
 Catheterization of umbilical artery or mesenteric vein
 After hepatic artery embolization

TABLE
93-6**Hepatic Calcification****INFECTIONS**

Histoplasmosis
 Tuberculosis
 Coccidioidomycosis
 Brucellosis
 Gumma
 Echinococcal cyst, *Armillifer* infestation
 Chronic amebic or pyogenic abscess
 Cytomegalovirus or *Toxoplasma* infection
 Chronic granulomatous disease of childhood
Clonorchis sinensis infection, cysticercosis, filariasis, paragonimiasis

VASCULAR LESIONS

Hepatic artery aneurysm
 Portal vein thrombosis
 Hematoma

BENIGN TUMORS

Cyst
 Cavernous hemangioma
 Capsule of regenerative nodules
 Infantile hemangioendothelioma

PRIMARY MALIGNANT TUMORS

Hepatoma, especially fibrolamellar
 Hepatoblastoma
 Cholangiocarcinoma

METASTATIC TUMORS

Mucinous carcinoma of the colon, breast, or stomach
 Ovarian carcinoma
 Melanoma
 Mesothelioma
 Osteosarcoma
 Carcinoid
 Leiomyosarcoma
 Teratoma
 Thyroid carcinoma
 Chondrosarcoma
 Neuroblastoma

BILIARY TREE

Calculus
 Cholangiocarcinoma
 Ascariasis

TABLE 93-9 Gas in the Biliary Tract

Sphincterotomy
 Gallstone erosion
 Patulous sphincter in elderly patient
 Cholecystoenterostomy
 Choledochenterostomy
 Spontaneous biliary fistula to the colon or duodenum by gallstones
 Perforating duodenal ulcer
 Trauma
 Carcinoma of the gallbladder, colon, stomach, pancreas, duodenum, ampulla, bile duct
 Diverticulitis
 Crohn's disease fistula
 Emphysematous cholecystitis
 Cholecystojejunostomy
 Pancreatitis
Strongyloides infection
 Incompetent sphincter of Oddi
Ascariasis lumbricoides infection
Clonorchis sinensis infection
 Ruptured amebic abscess
 Common duct entry into duodenal diverticulum
 Metastases
 Lymphoma

TABLE 93-12 Focally Increased Hepatic Echogenicity**COMMON**

Hemangioma
 Metastases
 Focal steatosis
 Adenoma
 Focal nodular hyperplasia
 Abscess
 Hematoma or laceration
 Hepatocellular carcinoma
 Fissures

UNCOMMON

Cytomegalovirus or *Candida* infection
 α_1 -Antitrypsin deficiency
 Lipoma
 Angiomyolipoma
 Infarct
 Regenerative nodules of cirrhosis
 Radiation therapy
 Omentum inserted into bed of hepatic resection
Echinococcus multilocularis infection
 Hemangioendothelioma

TABLE 93-10 Hepatic Vein Dilation**COMMON**

Right-sided heart failure
 Constrictive pericarditis
 Hepatic venous thrombus
 Inferior vena cava obstruction or thrombus
 Tricuspid atresia or stenosis
 With Valsalva maneuver in normal young patient

UNCOMMON

Right atrial tumor

TABLE 93-13 Diffusely Decreased Hepatic Echogenicity**COMMON**

Acute viral hepatitis
 Schistosomiasis (early)
 Malignant infiltration

UNCOMMON

Leukemia
 Lymphoma

APPARENT

End-stage renal disease
 Amyloid
 Nephrocalcinosis
 Myoglobinuric renal failure

Ultrasound

TABLE 93-11 Diffusely Increased Hepatic Echogenicity ("Bright Liver")**COMMON**

Fatty infiltration
 Cirrhosis
 Acute alcoholic hepatitis
 Severe viral or drug-induced hepatitis
 Diffuse malignant infiltration
 Chronic right-sided heart failure
 AIDS
 Technical artifact

UNCOMMON

Glycogen storage disease
 Gaucher's disease
 Miliary tuberculosis
 Mononucleosis
 Portal tract fibrosis
 Wilson's disease
 Lymphoma
 Sarcoidosis

TABLE 93-14 Hepatic Pseudolesions on Ultrasound Studies

Diaphragmatic leaflets: peripheral echogenic pseudolesion may simulate mass
 Falciform ligament: echogenic "mass" (pseudolesion) in left lobe
 Focal fatty infiltration: echogenic pseudolesion may simulate metastases
 Focal hepatic sparing in steatosis: hypoechoic pseudolesion often seen in porta
 Perihepatic fat may invaginate liver, causing hyperechoic masses
 Ligamentum venosum: fibrous tissue attenuates sound, causing hypoechoic pseudolesion in caudate lobe
 Gallbladder inflammation: hypoechoic hepatic pseudolesion in adjacent parenchyma

TABLE 93-15 Intrahepatic Acoustic Shadowing**LINEAR OR BRANCHING SHADOWING**

Intrabiliary air
Portal venous air
Intraductal stones

FOCAL SHADOWING

Gas: abscess, necrotic tumor, sequela of tumor embolization or of biopsy
Calcification: metastases, granulomas, abscess, aneurysm, parasites
Refractile artifacts: junction of vessels, gallbladder neck
Foreign material: surgical clips, drains, catheters, stents, sponges

TABLE 93-16 Hypoechoic or Anechoic Focal Masses**COMMON**

Cysts
Polycystic liver disease
Bilomas
Focal sparing in steatosis
Abscesses
Hematomas (early)
Metastases, especially colon, ovary, melanoma, sarcoma
Primary hepatic tumors
Post-traumatic cysts
Hydatid cysts

UNCOMMON

Caroli's disease
Extramedullary hematopoiesis
Focal hepatitis
Focal hepatic necrosis
Radiation therapy (early)
Cavernous hemangiomas
Hepatomas
Intrahepatic gallbladder

TABLE 93-17 Multiseptate Cystic Masses**COMMON**

Metastases
Simple cysts complicated by infection or hemorrhage

UNCOMMON

Teratoma
Cystic hepatoblastoma
Infantile peliosis hepatis
Hepatic hamartoma
Biliary cystadenoma

TABLE 93-18 Hyperechoic Masses with Acoustic Enhancement

Hemangioma
Hepatoma
Carcinoid metastases
Adenoma or hepatoma in glycogen storage disease

TABLE 93-19 Anechoic, Smooth-Walled Masses with Acoustic Enhancement

Cyst
Polycystic disease
Caroli's disease
Choledochal cyst
Hydatid cyst

TABLE 93-20 Complex Masses**SEPTATE**

Hydatid cyst
Biliary cystadenoma
Ovarian carcinoma metastases

NO SEPTA

Abscess
Tumor

BULL'S-EYE LESIONS

Metastases
Abscess
Primary neoplasm

TABLE 93-21 Prominent Periportal Echoes**COMMON**

Acute cholecystitis
Chronic cholecystitis
Cholangitis
Oriental cholangiohepatitis
Cholangiocarcinoma
Sclerosing cholangitis
Hepatocellular carcinoma
Air in biliary tree

UNCOMMON

Cystic fibrosis
Schistosomiasis
Lymphoma
Infectious mononucleosis

IN NEONATES

Biliary atresia
Acute hepatitis
Cytomegalovirus infection
Nesidioblastosis
 α_1 -Antitrypsin deficiency
Idiopathic neonatal jaundice

TABLE 93-22 Echo Patterns of Hepatic Metastases

ECHOGENIC LESIONS
Any carcinoma but especially from the gastrointestinal tract, pancreas, hepatoma, breast, and vascular primaries (islet cell, carcinoid, choriocarcinoma, renal cell carcinoma)
HYPOECHOIC LESIONS
Homogeneous tumor-like lymphomas, some breast and lung cancers
CYSTIC METASTASES
Mucin-secreting metastases from neoplasms of the ovary, colon, pancreas, or stomach
Central necrosis of any lesion, especially sarcomas
DENSELY ECHOGENIC LESIONS, WITH SHADOWING
Mucinous carcinoma of the colon
Adenocarcinoma of the stomach
Pseudomucinous cystadenocarcinoma of the ovary
Cystadenocarcinoma of the pancreas
Adenocarcinoma of the breast
Melanoma
BULL'S-EYE OR TARGET PATTERN
Lung cancer
INFILTRATIVE PATTERN
Breast cancer
Lung cancer
Melanoma

TABLE 93-23 Dampening of Hepatic Vein Doppler Waveform

Cirrhosis
Passive hepatic congestion
Budd-Chiari syndrome
Various parenchymal abnormalities of liver
Extrinsic compression of hepatic veins

TABLE 93-24 Transjugular Intrahepatic Portosystemic Shunt Malfunction

DIRECT SIGNS
No flow—consistent with shunt occlusion or thrombosis
Low-velocity flow—especially at portal venous end of shunt
Change in peak shunt velocity—increase or decrease from baseline of 50 cm/s
Reversal of flow in hepatic vein
Hepatopetal intrahepatic portal venous flow
SECONDARY SIGNS
Reappearance of varices
Reaccumulation of ascites
Reappearance of recanalized paraumbilical vein

Computed Tomography

TABLE 93-25 Focal Hypodense Lesion: Precontrast and Postcontrast Scan Appearance

Lesion	Appearance after Contrast Medium Administration
Metastases	Irregular enhancement or none
Malignant primary tumors	
Hepatoma	
Hemangioendothelioma	
Hemangiosarcoma	
Intrahepatic cholangiocarcinoma	
Lymphoma	
Cholangiocarcinoma	Irregular enhancement
Benign tumors	
Hemangioma	75% Peripheral enhancement 10% Central enhancement 74% Progressively isodense on delayed scans 24% Partially isodense on delayed scans 2% Hypodense on delayed scans
Adenoma	85% Hyperdense during arterial phase but rapidly becomes isodense or hypodense (1 minute)
Focal nodular hyperplasia	Most hyperdense during arterial phase but rapidly becomes isodense or hyperdense (1 minute); a low-density central scar may be present, but it is also seen in fibrolamellar hepatomas and hemangiomas
Cysts	Margins of cyst are more clearly defined
Benign simple cysts	
Polycystic liver disease	
von Hippel-Lindau disease	
Abscesses	Often show peripheral enhancement
Pyogenic	May show a "spoke-wheel" enhancement pattern
Fungal	
Amebic	May show peripheral enhancement
Radiation injury	No change
Focal fatty infiltration	No change
Infarction	No change
Laceration	No change
Old hematoma	No change
Biloma	No change
Caroli's disease	No change
Choledochal cyst	No change
Focal biliary dilation	No change
Intrahepatic extension of pseudocyst	No change

TABLE 93-26 Diffusely Dense Liver

Hemochromatosis
Hemosiderosis
Glycogen storage disease
Amiodarone treatment
Gold therapy
Chronic arsenic poisoning

TABLE 93-27 Focal Hypodense Lesion: Noncontrast Scans

Mucinous metastases: colon, ovary, stomach, pancreas (primary)
 Primary hepatic tumors: hepatoma (especially fibrolamellar),
 hepatoblastoma, hemangioendothelioma
 Benign hepatic tumors: hemangiomas
 Infections

ACUTE HEMORRHAGE

Hematoma

VASCULAR

Budd-Chiari syndrome with spared parenchyma
 Portal vein thrombosis with spared parenchyma

Focal fatty infiltration
Hepatoma
Hepatic adenoma

UNCOMMON

Cavernous hemangioma

RARE

Metastatic liposarcoma or myxoid liposarcoma

TABLE 93-40 Wedge-Shaped Signal Alterations

T1 HYPERINTENSITY

Irregular fatty infiltration

T2 HYPERINTENSITY

Hepatocellular carcinoma with peripheral ischemia or infarction
Metastases with wedge pattern of edema
Primary or secondary portal infarction
THID (transient hepatic intensity difference)

TABLE 93-41 Liver Lesions with Circumferential Rim

HYPOINTENSE RIM ON T1-WEIGHTED IMAGE

Chronic hematoma (hemosiderin)
Hepatocellular carcinoma (pseudocapsular rim is thin)
Hydatid cyst (thick, homogeneous rim, no perilesional edema)
Amebic liver abscess (concentric rims; rim of collagen)

HYPOINTENSE RIM ON T2-WEIGHTED IMAGE

Metastases (peritumoral edema with double ring pattern)
Liver abscess (one or two concentric rings of mixed signal intensity)
Subacute to chronic parenchymal hematoma (white rim also seen on T1-weighted images)

NO RIM

Simple cyst
Cavernous hemangioma
Adenoma
Focal nodular hyperplasia

TABLE 93-42 Central Scars in Primary Liver Tumors

Cavernous hemangioma: hypointense or hyperintense T2-weighted image (can be either inflammatory or fibrous scar)
Hepatic adenoma: variable signal
Focal nodular hyperplasia: hypointense T1-weighted image, hyperintense T2-weighted image (inflammatory scar)
Fibrolamellar hepatocellular carcinoma: hypointense T1-weighted image, hyperintense T2-weighted image (fibrotic repair of scar)

Nuclear Scintigraphy

Imaging Findings in Specific Hepatic Diseases

TABLE
93-52

Cirrhosis and Portal Hypertension

MORPHOLOGIC CHANGES SEEN ON ULTRASOUND, CT, AND MRI STUDIES

Large liver early
Shrunken liver late, prominent fissures
Enlarged caudate lobe and lateral segment of left lobe
Caudate-to-right lobe ratio >0.65 on transverse images
Surface nodularity and indentations (regenerative nodules)
Altered gallbladder angle
Colonic and omental interposition
Signs of portal hypertension: varices, splenomegaly, ascites

ULTRASOUND

Increased echogenicity
Increased sound attenuation
Heterogeneous echo architecture
Decreased definition of portal and hepatic veins
Dilated hepatic arteries, portal vein, coronary veins, superior mesenteric vein
Thick lesser omentum in children
Increased incidence of gallstones
Regenerative nodules: hypoechoic areas with echogenic borders (rare)
Siderotic nodules in spleen: hyperechoic masses (rare)

Doppler Findings in Portal Hypertension

Dilated portal vein with decreased respiratory variation
Hepatofugal flow in portal system
Varices
Recanalized umbilical vein
Decreased variability of hepatic venous flow
Increased flow in superior mesenteric, splenic, and portal veins
Increased splenic and superior mesenteric artery flow
Resistive index of hepatic arterial flow >0.78

Computed Tomography

Fatty infiltration in early cirrhosis
Dense liver in hemochromatosis
Inhomogeneous enhancement
Portal and hepatic veins possibly compressed and difficult to visualize
Intrahepatic arterial-portal fistulas
Regenerative nodules
Portal hypertension
Varices
Increased density mesenteric fat

MR Imaging

Regenerative nodules: low-intensity areas on T2-weighted images (hemosiderin)
No appreciable change in hepatic signal in fibrosis
Siderotic nodules in spleen

ANGIOGRAPHY

Stretched hepatic artery branches
Corkscrewing: enlarged, tortuous hepatic arteries
Mottled parenchymal phase
Shunting between hepatic artery and portal vein
Delayed emptying into venous phase
Pruned hepatic vein branches

TABLE
93-53

Fatty Infiltration

COMPUTED TOMOGRAPHY

Liver less dense than spleen; spleen normally 6-12 HU less dense than liver
Rapid appearance and disappearance of fat
"Hyperdense" intrahepatic vascular structures
Possible fat deposition in a focal, lobar, segmental, or bizarre geographic distribution
Spared areas: caudate lobe, quadrate lobe, subcapsular, gallbladder fossa

ULTRASOUND

Increased hepatic echogenicity and increased number of echogenic foci in liver
Increased attenuation of sound with poor penetration of the posterior liver
Poor visualization of hepatic and portal veins and diaphragm
Focal fat presentations: multiple confluent hypoechoic lesions; hypoechoic ("skip") nodules; irregular hyperechoic and hypoechoic skip areas may show rapid change in time; do not produce contour abnormalities; do not alter course or caliber of regional vessels

MR IMAGING

No significant change in T1-weighted or T2-weighted images
On opposed-phase images, spin-echo (Dixon's technique), fat suppression techniques, and short T1 inversion recovery images, low signal intensity of fat

TABLE
93-54

Viral Hepatitis

ULTRASOUND

Acute Hepatitis

Hepatosplenomegaly
Decreased hepatic echogenicity
Increased brightness of portal vein walls ("starry sky" pattern)
Mural thickening of gallbladder; hypotonic and dilated gallbladder

Chronic Hepatitis

Increased hepatic echogenicity
Coarsened parenchymal texture
Loss of definition of portal vein walls
Adenopathy in hepatoduodenal ligament in chronic active hepatitis

COMPUTED TOMOGRAPHY

Hepatosplenomegaly
Periportal lucency
Mural thickening of gallbladder
Adenopathy in hepatoduodenal ligament in chronic active hepatitis

MR IMAGING

Hepatosplenomegaly
Periportal hyperintensity on T2-weighted images
Increased T1 and T2 relaxation times of parenchyma

NUCLEAR SCINTIGRAPHY

Hepatosplenomegaly
Colloid shift
Heterogeneous uptake
Delayed parenchymal clearance and blood pool tracer retention on iminodiacetic acid scans

TABLE
93-55**Budd-Chiari Syndrome****MR IMAGING**

Constriction or loss of a signal void in the intrahepatic or suprahepatic inferior vena cava
 Loss in caliber or absence of the hepatic vein signal void
 Comma-shaped, intrahepatic, hypointense collateral vessels
 Nodular liver, with or without hypointense regenerative nodules
 Intrahepatic portal vein thrombosis
 Enlarged caudate lobe, ascites, inhomogeneous hepatic parenchyma

ULTRASOUND

Stenosis, thrombosis, or nonvisualization of hepatic veins
 Thick, echogenic hepatic vein walls
 Narrowed inferior vena cava
 Intrahepatic collateral vessels or extrahepatic anastomoses
 Ascites, enlarged caudate lobe

COMPUTED TOMOGRAPHY**Noncontrast Scans**

Diffuse hypodensity associated with global liver enlargement and ascites
 Caudate lobe may appear hyperdense
 Hyperdense thrombus in inferior vena cava

Contrast Scans

Patchy contrast enhancement because of hepatic congestion
 Central liver (caudate, portions of left lobe) hyperdense; periphery hypodense
 Later ("flip-flop" pattern), center washes out, becomes hypodense relative to liver periphery, which slowly accumulates contrast medium
 Portal vein thrombus
 Nodular regenerative hyperplasia

ANGIOGRAPHY

Absence of main hepatic veins
 "Spider web" appearance of collateral intrahepatic veins or lymphatics
 Inhomogeneous, dense, prolonged, intense hepatogram with fine mottling
 Stretching and draping of intrahepatic arteries with hepatomegaly
 Large lakes of sinusoidal contrast medium accumulation
 Bidirectional or hepatofugal portal vein flow
 Thrombus in hepatic veins or inferior vena cava
 Impairment of caval flow because of diffuse hepatomegaly
 Membranous obstruction of the cava at the ostia of the hepatic veins
 Diminished or hepatofugal flow to involved segments during arterial portography

NUCLEAR SCINTIGRAPHY

Enlarged caudate lobe with increased uptake
 Diffusely decreased uptake in remainder of liver
 Hepatosplenomegaly
 Wedge-shaped focal peripheral defects
 Colloid shift to spleen and bone marrow

TABLE
93-56**Hemochromatosis****COMPUTED TOMOGRAPHY**

Diffuse increase in density up to 80-140 HU
 Hepatic veins and portal veins stand out on noncontrast scans

MR IMAGING

Shortened T1 and T2 relaxation times, T2 shortening effect predominating, with significant signal loss in liver

ULTRASOUND

Nonspecific findings that relate to secondary fibrosis and cirrhosis

NUCLEAR SCINTIGRAPHY

Discordant sulfur colloid and iminodiacetic acid scans early: iminodiacetic acid scan normal; sulfur colloid scan with diffuse parenchymal damage

TABLE
93-57**Hepatocellular Adenoma****COMPUTED TOMOGRAPHY**

Round masses of decreased density, necrotic areas (30%-40%)
 Hyperdense areas of fresh intratumor hemorrhage (22%-55%)
 Variable patterns of enhancement; not enhanced to the same degree as normal liver

ULTRASOUND

When small, well-demarcated and solid echogenic structure
 Well-defined perilesional and intralesional blood vessels with 2- to 4-kHz shifts
 When large, complex hyperechogenic and hypoechogenic heterogeneous mass with anechoic areas

MR IMAGING

Inhomogeneous on all pulse sequences
 Fat within mass, producing hyperintense areas on T1-weighted images
 Sheets of hepatocytes isointense on T2-weighted images
 Areas of necrosis and hemorrhage hyperintense on T2-weighted images

NUCLEAR SCINTIGRAPHY

No gallium uptake
 Photopenic area on sulfur colloid and hepatobiliary scans surrounded by rim of increased uptake

ANGIOGRAPHY

Hypervascular mass that is homogeneous but does not stain intensely in capillary phase
 Hypovascular or avascular regions because of hemorrhage or necrosis
 Enlarged hepatic artery with feeders at tumor periphery (50%)
 Neovascularity

TABLE
93-58**Cavernous Hemangioma****ULTRASOUND**

Hyperechoic, homogeneous mass with discrete margins, usually <3 cm
 When larger, possible hypoechoic center, which may appear lacelike or granular
 Possible acoustic enhancement
 Stable size and appearance

COMPUTED TOMOGRAPHY

Well-circumscribed, spherical to ovoid, low-density mass on noncontrast scans
 Peripheral enhancement with vascular nodules, progressive centripetal flow, complete fill-in on delayed images 3-30 minutes after bolus (55%-89%)
 Complete (75%), partial (24%), or no (2%) fill-in isodensity in delayed phase

MR IMAGING

Well marginated
 Isointense or minimally hypointense signal on T1-weighted images
 T2 relaxation time longer than 80 ms
 No fibrous pseudocapsule
 Peak enhancement >2 minutes after injection of gadolinium diethylenetriaminepentaacetic acid
 Marked hyperintensity at 5-minute delay on T1-weighted image after contrast medium administration
 Variable central scar signal intensity on T1-weighted and T2-weighted images because of clot or fibrous tissue
 Progressive signal hyperintensity with increased T2 weighting
 No daughter nodules
 Intratumoral septa uncommon
 No hepatic venous, portal, or caval tumor thrombi

NUCLEAR SCINTIGRAPHY

Cold region during scintigraphic angiography on technetium Tc 99m-labeled erythrocyte scans
 Increased activity on delayed images at 1-2 hours
 Cold defect on sulfur colloid scans

ANGIOGRAPHY

Dense opacification of dilated, well-circumscribed, irregular, punctate vascular lakes and puddles in late arterial and parenchymal phase, beginning at the periphery
 Normal-sized feeders without arteriovenous shunting
 Contrast medium persistence late into venous phase

TABLE
93-59**Hepatocellular Carcinoma****ULTRASOUND**

Large tumor hyperechoic (59%)
 Small tumor hypoechoic (26%); often see thin, peripheral hypoechoic halo corresponding to fibrous capsule
 Mixed echogenicity in diffuse form (15%)
 Portal vein invasion (25%-40%)
 Hepatic vein invasion (16%)
 Invasion of inferior vena cava
 Hepatomegaly and ascites
 Characteristic high-flow Doppler signals, with shifts ≥ 4.5 kHz
 Fine blood flow network (branching pattern)

COMPUTED TOMOGRAPHY

Hypodense mass
 Circular zone of radiolucency surrounding mass
 Enhancement during arterial phase (80%)
 If sufficient arteriovenous shunting, early visualization of hepatic veins and cava
 Isodense on delayed scans (10%)

MR IMAGING

Poorly marginated
 Isointense to minimally hyperintense (50%) on T1-weighted images because of fat content
 T2 relaxation time <80 ms
 Pseudocapsule hypointense on T1-weighted and T2-weighted images
 Moderate peak enhancement
 Faint enhancement at 5-minute delay after contrast agent administration
 Hypointense central scar on T1-weighted and T2-weighted images
 Less pronounced hyperintensity with progressive T2 weighting
 Daughter nodules present
 Intratumoral septa common
 Intermediate signal intensity tumor thrombi in cava, portal vein, or hepatic vein on T1-weighted images

ANGIOGRAPHY

Enlarged arterial feeders, coarse neovascularity, vascular lakes, arterioportal shunts, and dense tumor stain in differentiated hepatocellular carcinoma
 Vascular encasement, fine neovascularity, displacement, and corkscrewing of vessels in cirrhosis and anaplastic hepatomas
 With tumor invasion of portal vein, "thread and streaks" appearance, linear parallel vascular channels

NUCLEAR SCINTIGRAPHY

On sulfur colloid scan, single cold spot (70%), multiple defects (15%-20%), or heterogeneous distribution (10%)
 Cold nodule on iminodiacetic acid scan
 On gallium scan, avid accumulation in 70%-90%

TABLE 93-60 Focal Nodular Hyperplasia

COMPUTED TOMOGRAPHY Homogeneous mass of slightly decreased attenuation on noncontrast scans Isodense or hypodense on bolus injection of contrast material Markedly hyperdense on arterial phase; may be isodense on portal venous phase because of rapid washout Central scar may be hyperdense or hypodense on arterial phase, hyperdense on delayed images because of delayed washout within myxomatous stroma	MR IMAGING Isointense on T1-weighted and T2-weighted images (80%) Isointense on T1-weighted images and slightly hyperintense on T2-weighted images (20%) Margins poorly defined or invisible Central scar is hypointense on T1-weighted images and hyperintense on T2-weighted images (95%) (compare fibrolamellar hepatoma, in which central scar is hypointense on T1-weighted and T2-weighted images, and hepatoma, in which central scar is rare)
ULTRASOUND Hypoechoic or hyperechoic homogeneous mass, often isoechoic, subtle, difficult to differentiate in echogenicity from adjacent liver Central scar appears as a hypoechoic linear or stellate area within the central portion of the mass Well-developed peripheral and central blood vessels creating a spoke-wheel appearance Predominant arterial signals centrally with a midrange (2-4 kHz) shift	ANGIOGRAPHY Hypervascular mass (90%) with intense capillary blush Enlarged main feeding artery with central blood supply (spoke-wheel pattern, 33%) Decreased vascularity in central stellate fibrous scar NUCLEAR SCINTIGRAPHY Normal sulfur colloid scan (30%-55%), cold spot (40%), or hot spot (10%) Iminodiacetic acid scan: normal or increased uptake (40%-70%) or cold spot (60%)

Endoscopic Retrograde Cholangiopancreatography

Historical Perspective

The pancreas was one of the last organs in the abdomen to receive the attention of anatomists, physiologists, physicians, and surgeons. Located in the “straggling mesenchyme” of the retroperitoneum, the pancreas has in the past been called the hermit or hidden organ of the abdomen.¹ The pancreas was first described in the Talmud and depicted as the “finger of the liver” between 200 BC and AD 200. Ruphos named this organ the pancreas (Greek: *pan*, meaning “all”; *kreas*, meaning “flesh”) shortly thereafter.² More than a millennium passed before anatomic descriptions were completed.

Wirsung of Padua demonstrated the pancreatic duct in 1642, and Santorini of Venice described the accessory duct in 1724. The papilla of Vater was described by A. Vater in 1720. In 1887, Oddi described the complex musculature of the sphincter bearing his name. The histologic structure of the pancreas was described by Langerhans in 1869. The role of the pancreas in digestion was first suggested by Bernard in 1850, and the connection between diabetes and the pancreas was established in the 1890s. Surgery for pancreatic disease was not popular until the pioneering work of Whipple in the 1930s.³

The pancreas also remained a hidden organ for the radiologist for decades. Indirect signs of pancreatic disease on plain films and barium studies were usually present only in advanced disease. The 1970s brought endoscopic retrograde cholangiopancreatography (ERCP) and angiography to the

fore. Computed tomography (CT), ultrasound, and magnetic resonance imaging (MRI) now routinely provide superb visualization of the gland noninvasively.⁴ Endoscopic ultrasound is a useful adjunct to cross-sectional imaging in evaluating for pancreatic disease and allows pancreatic biopsy when it is indicated.

Normal Anatomy

The pancreas is an unpaired accessory digestive gland that has both exocrine and endocrine functions. It is a slender, soft, lobulated organ that in the adult measures approximately 15 to 25 cm in length, 3 to 5 cm in height, and 1.5 to 3.5 cm in thickness and weighs 70 to 110 g.^{5,6} It has a pale, yellow-tan surface that is finely nodular and firm to palpation.

TOPOGRAPHY

The pancreas lies within the anterior pararenal space (Fig. 94-1). The pancreatic head has a constant relationship with the duodenum, with its right lateral border nestled in the duodenal sweep.⁷ The head is the thickest portion of the gland; it gives rise to the uncinate process, which projects like a hook, dorsal to the superior mesenteric vein. The pancreatic neck lies immediately anterior to the confluence of the splenic and superior mesenteric veins. The neck narrows behind the pylorus, then widens as it becomes the body. The body arches anteriorly and laterally to cross the spine and may be thinner than the pancreatic head and tail as it does.^{8,9} The body bulges up in the pancreatic tubercle almost to the level of the celiac axis. The tail is not well demarcated from the body as it extends to the splenic hilum.¹⁰

The shape, position, and axis of the pancreas are variable and are influenced by age, body habitus, previous surgery, and organomegaly.⁹ The head usually lies at the level of L1-L2, and the body crosses the spine at L1; the tail is located more superiorly in the region of the splenic hilum. The longitudinal axis of the pancreas is about 20 degrees in relationship to the transverse plane¹⁰ (Fig. 94-2). The axis of the pancreas is occasionally transverse, and even less commonly the tail may lie caudal to the head. If the left kidney is congenitally or surgically absent, the tail often lies in a posteromedial position, adjacent to the spine. The pancreas can be shaped like an L, S, or inverted V.¹⁰

The gastric body and antrum lie anterior to the body and tail of the pancreas, and the pylorus is located ventral to the pancreatic neck. The duodenum lies along the right lateral border of the pancreatic head; it also passes inferior to the head, body, and tail. The spleen lies along the lateral and superior aspect of the pancreatic tail. The right kidney and adrenal gland are located posterior to the pancreatic head, and the left kidney

Figure 94-1 Anatomic relationships of the pancreas. (From Meyers MA: *Dynamic Radiology of the Abdomen*. New York, Springer-Verlag, 1988, p 57.)

Figure 94-2 Normal pancreatic orientation and appearances of the pancreatic head. **A.** Normal pancreatic dimensions. **B.** Normal pancreatic head configurations. (**A** from Zylak CJ, Pallie W: *Correlative anatomy and computed tomography: A module on the pancreas and posterior abdominal wall*. *RadioGraphics* 1:61–84, 1981. **B** from Mortelet KR, Rocher TC, Stretter JL, et al: *Multimodality imaging of pancreatic and biliary congenital anomalies*. *RadioGraphics* 26:715–731, 2006.)

and adrenal gland are dorsal and occasionally caudal to the tail. Depending on its size, the left lobe of the liver may lie anterior to the pancreatic body. The gallbladder is positioned ventral to the pancreatic head. The transverse colon lies anterior and generally inferior to the pancreas. The small bowel usually lies inferior to the level of the pancreas but occasionally can lie ventral to the tail.^{11,12}

Nearly all of the pancreas is retroperitoneal; a nonperitonealized bare area results from the reflection of the posterior parietal peritoneum to form the two leaves of the transverse mesocolon and the posterior inferior margin of the lesser sac (Fig. 94-3). The transverse mesocolon originates where the hepatic flexure of the colon crosses ventral to the second portion of the duodenum. The bare area begins as a broad strip across the infra-ampullary portion of the descending duodenum and continues across the head, body, and tail of the pancreas. The pancreatic tail, after extending across the left kidney, is actually an intraperitoneal structure incorporated within the leaves of

the splenorenal ligament. The root of the small bowel mesentery originates inferior to the pancreatic body and is contiguous with the transverse mesocolon.^{7,13} Therefore, pancreatic processes may affect the stomach and duodenum by direct spread and the small bowel loops and colon through the small bowel mesentery and transverse mesocolon (see Fig. 94-3).

COMMON BILE DUCT

The common bile duct enters the head of the pancreas after it passes posterior to the first part of the duodenum in the hepatoduodenal ligament. It passes inferiorly and dorsally, embedded in the posterior surface of the pancreatic head, to join the pancreatic duct of Wirsung. This segment runs a short intramural course before it enters the posteromedial aspect of the duodenum through the major papilla of Vater (Fig. 94-4). The common bile duct is 7 cm long and has an average diameter of 7.4 mm.^{8,14,15}

Figure 94-3 The mesenteric, omental, retroperitoneal, and subperitoneal relationships of the pancreas: sagittal perspective. Pancreatic disease may spread into the lesser sac (1), transverse mesocolon (2), root of the small bowel mesentery (3), duodenum (4), and anterior pararenal space (5).

Figure 94-4 Extrahepatic biliary and pancreatic duct system. (From Tersingni R, Toledo-Pereyra LH: *Surgical anatomy of the pancreas*. In Toledo-Pereyra LH [ed]: *The Pancreas: Principles of Medical and Surgical Practice*. New York, Churchill Livingstone, 1985, pp 31–50.)

PANCREATIC DUCT

The pancreatic duct arises from the pancreatic tail and receives 20 to 35 short tributaries entering at right angles to its long axis as it courses toward the head. The duct lies midway between the superior and inferior margins of the pancreas and slightly more dorsally than ventrally. At the level of the major papilla, the main pancreatic duct (duct of Wirsung) courses horizontally to join the caudal surface of the common bile duct, forming the ampulla of Vater. The accessory pancreatic duct of Santorini drains the anterior and superior portion of the head of the pancreas either into the duodenum

at the minor papilla or into the main pancreatic duct (see Fig. 94-4). The minor papilla is often not patent, and the accessory duct may be partially or completely obliterated or have an anomalous connection with the duct of Wirsung.^{16,17} These anatomic variants in ductal anatomy are discussed more fully in Chapter 96.

ARTERIAL SUPPLY

Although the pancreatic parenchyma is well visualized on cross-sectional imaging, it is important to recognize and to define the major pancreatic vascular landmarks¹⁸ (Fig. 94-5). The arterial blood supply of the pancreas arises from the celiac trunk and the superior mesenteric artery. After originating from the celiac artery, the common hepatic artery courses to the right in proximity to the neck and subsequently the head of the pancreas. At this point, it divides into the proper hepatic artery, which enters the free edge of the hepatoduodenal ligament, and the gastroduodenal artery, which courses caudally to lie ventral and lateral to the pancreatic head. The gastroduodenal artery gives rise to the anterior and posterior superior pancreaticoduodenal arteries, which supply the head of the pancreas. These vessels help form the pancreatic arcade when they join the anterior and posterior inferior mesenteric arteries that arise separately or as a common trunk from the proximal portion of the superior mesenteric artery.^{5,11,14,19}

The splenic artery arises from the celiac artery and loops like a snake above and below the superior margin of the pancreas. It becomes more tortuous with age and occasionally becomes embedded within the pancreatic parenchyma. The pancreatic body and tail are supplied by the dorsal pancreatic artery, which arises from the splenic artery or as a fourth branch of the celiac trunk, as well as by the splenic, hepatic, or superior mesenteric arteries. The pancreatica magna is the largest of the series of superior pancreatic branches of the splenic artery.^{19,20}

The superior mesenteric artery arises from the anterior surface of the aorta, 1 to 2 cm below the celiac trunk. It courses caudal and dorsal to the neck of the pancreas, passing anterior to the uncinate process, where it serves as a major landmark for cross-sectional imaging. Displacement of the artery to the right of the aorta is a normal variant.²¹

The most frequent arterial anomaly of the upper abdomen is partial or complete replacement of either the right hepatic or the proper hepatic artery to the superior mesenteric artery. In these patients, the replaced hepatic artery passes cephalad and ventral to the pancreas, then anterior or posterior to the portal vein to reach the liver.²²

VENOUS DRAINAGE

The venous drainage of the pancreas is constant; the portal system serves as an essential landmark for localizing the pancreas on cross-sectional imaging.^{11,19} In general, the veins of the pancreas parallel the arteries and lie inferior to them (Fig. 94-6). Four pancreaticoduodenal veins form venous arcades that drain the pancreatic head and the duodenum. The inferior pancreaticoduodenal veins drain into the first jejunal branch of the superior mesenteric vein. The inferior pancreaticoduodenal veins are smaller than their superior counterparts; they are not commonly visualized on cross-sectional imaging. The posterior superior pancreaticoduodenal vein extends cephalad to join the

Figure 94-5 Schematic views of the arterial blood supply of the pancreas. (A and B from Tersingni R, Toledo-Pereyra LH: *Surgical anatomy of the pancreas*. In Toledo-Pereyra LH [ed]: *The Pancreas: Principles of Medical and Surgical Practice*. New York, Churchill Livingstone, 1985, pp 31–50.)

caudal aspect of the portal vein directly.^{21,22} The anterior superior pancreaticoduodenal vein runs horizontally to drain into either the gastroduodenal vein or the right gastroepiploic vein, both of which extend to the superior mesenteric vein.²³ Three to 13 small veins from the body and tail empty directly into the splenic vein, which follows a smooth arching course from the spleen to its junction with the superior mesenteric vein. The splenic vein parallels the splenic artery and lies in a groove along the dorsal and superior margin of the pancreas. It is a superb landmark for the posterior aspect of the pancreas, and long segments of this vessel can be seen on CT and ultrasound studies on a single image.²⁴ Rarely, the distal tip of the pancreatic tail can lie posterior to the vein, adjacent to the adrenal gland.²⁵

The splenic vein joins the superior mesenteric vein posterior to the neck of the pancreas and is seen as a round or oval

dilation to the right of the midline, posterior to the neck of the pancreas. The superior mesenteric vein courses anterior to the uncinate process just to the right of the superior mesenteric artery^{11,22} (see Fig. 94-6).

The portal vein is formed behind the pancreatic neck by the union of the splenic and superior mesenteric veins and continues superiorly and laterally toward the porta hepatis as the main extrahepatic portal vein, dorsal to the common bile duct and hepatic artery. In one third of the population, the inferior mesenteric vein enters at the confluence; in another third, it joins the splenic vein close to the junction; and in the remainder, it joins the superior mesenteric vein.⁸

LYMPHATICS

The lymph nodes of the pancreas are distributed along the major vascular pathways (Fig. 94-7). The lymphatic channels of the pancreas form a richly branched plexus that empties

Figure 94-6 Schematic views of the venous drainage of the pancreas. (A and B from Tersingni R, Toledo-Pereyra LH: *Surgical anatomy of the pancreas*. In Toledo-Pereyra LH [ed]: *The Pancreas: Principles of Medical and Surgical Practice*. New York, Churchill Livingstone, 1985, pp 31–50.)

Figure 94-7 Major regional nodal groups of the pancreas. (From Tersingni R, Toledo-Pereyra LH: *Surgical anatomy of the pancreas*. In Toledo-Pereyra LH [ed]: *The Pancreas: Principles of Medical and Surgical Practice*. New York, Churchill Livingstone, 1985, pp 31–50.)

in multiple directions. The extensive network of lymphatic vessels and lymph nodes draining the pancreas provides egress to tumor cells arising from the pancreas and contributes to the fact that pancreatic cancer often presents with positive lymph nodes and a high incidence of local recurrence after resection. The anatomy of the lymphatics suggests that partial removal of the pancreas for cancer may not be sufficient because of the direct connections between different lymphatic chains.^{5,8,15,19,20}

The suprapancreatic and intrapancreatic lymphatic chains receive branches from the neck, body, and portions of the pancreatic tail. Branches from the posterior surface of the head and neck drain into the pancreaticoduodenal and juxta-aortic nodes. The posterior surface of the pancreatic body drains into the suprapancreatic and intrapancreatic nodes. The pancreatic tail drains into the nodes of the splenic hilum and gastropancreatic fold. Some drainage from the pancreatic head and proximal body enters the nodes in the porta hepatis and may extend inferiorly toward the superior mesenteric, mesocolic, and para-aortic nodal chains. The suprapancreatic nodes are closely related to the splenic artery and vein; the intrapancreatic chain is adjacent to the leaves of the transverse mesocolon.

NERVE SUPPLY

It is important to appreciate the nerve supply of the pancreas (Fig. 94-8) in planning celiac nerve blocks for control of pain resulting from pancreatic carcinoma or chronic pancreatitis.²⁶ The pancreas receives sympathetic innervation by way of the splanchnic nerves and parasympathetic innervation from the vagus nerve. The sympathetic nerves carry the pain (visceral afferent) fibers. They pierce the diaphragmatic crura to enter the celiac plexus and celiac ganglion that surround the celiac artery. The superior mesenteric ganglia and plexus surround the superior mesenteric artery. Chemical extirpation of the celiac ganglion interrupts afferent pain fibers from both the sympathetic and the parasympathetic systems and can be accomplished by injection of the chemical agent between the celiac artery and the superior mesenteric artery either antecrurally or retrocrurally.²⁶⁻²⁸

Radiologic Techniques

PLAIN RADIOGRAPHS

In patients with suspected pancreatic disease, plain radiographs are obtained chiefly to exclude other conditions, such as obstruction or a perforated duodenal ulcer that may simulate pancreatitis.²⁹⁻³² Oblique views are often helpful in patients with chronic pancreatitis to detect calcifications that may be obscured by the spine on the anteroposterior view.^{30,32,33}

CONTRAST STUDIES

Before the advent of cross-sectional imaging, angiography, ERCP, and barium studies were the major means of evaluating the pancreas. Although barium studies are less important now in evaluation of the pancreas, the following areas should still be carefully evaluated in patients with suspected pancreatic disease. The posterior gastric wall, the distal duodenum, and the duodenojejunal junction can be abnormal with lesions of the

Figure 94-8 Nerve supply of the pancreas. (From Tersingni R, Toledo-Pereyra LH: *Surgical anatomy of the pancreas*. In Toledo-Pereyra LH: *The Pancreas: Principles of Medical and Surgical Practice*. Churchill Livingstone, New York, 1985, pp 31-50.)

pancreatic tail and body; the greater curvature of the gastric antrum and medial aspect of the descending duodenum can provide clues for lesions arising in the pancreatic head and neck. Barium enema examination may reveal abnormalities of the colon caused by disease spread through the transverse mesocolon or at the splenic flexure caused by disease carried by the phrenicocolic ligament.^{13,30,31}

ULTRASOUND

Sonography is a means of noninvasively evaluating the pancreas, particularly in thin patients. It is fast, safe, and inexpensive; it can be done portably; and it requires little preparation or cooperation of the patient and no administration of contrast medium.³⁴ However, ultrasound can be limited by patient body habitus and is dependent on the level of experience of the operator. Ultrasound examination of the pancreas is best performed on the fasting patient to reduce the amount of gas and food in overlying bowel. Real-time equipment with the highest frequency transducer (5-8 MHz) possible should be used.

Examination Techniques

Scans of the pancreas should first be performed with the patient supine and the transducer turned into a modified transverse plane angled cephalad toward the spleen (Fig. 94-9). The long axis of the pancreas is seen anterior to the splenic vein and confluence of the superior mesenteric and splenic veins. The pancreatic head and neck sweep around the superior mesenteric vein, forming the retrovenous, hooklike uncinate process. The common bile duct is often imaged axially within the pancreatic head, and the gastroduodenal artery may be seen along the anterolateral aspect of the pancreatic head. The gas-filled or fluid-filled duodenum, stomach, colon, aorta, inferior vena cava, superior mesenteric artery, and left renal vein are interrogated in this projection as well. The lesser sac, which lies between the posterior gastric wall and pancreas, is best seen in this plane and should be scanned for fluid, masses, or calcifications.³⁵⁻³⁸

Parasagittal scans of the pancreas should begin where the portal vein merges with the longitudinally oriented superior mesenteric vein. The neck of the pancreas in transverse section is seen anterior to this confluence. The uncinate process lies posterior to the superior mesenteric vein. The pancreatic head can be seen to the right of the superior mesenteric vein, with the common bile duct located posteriorly and the gastroduodenal artery sometimes visualized anteriorly. To the left of the superior mesenteric vein, the pancreatic body and proximal portion of the tail are found anterior to the splenic vein and slightly inferior to the splenic artery.³⁹⁻⁴³

With meticulous technique and attention to detail, diagnostic scans of the pancreas can be obtained in 90% of cases. Several maneuvers can improve sonographic visualization of the pancreas.⁴⁴⁻⁴⁹ Deep inspiration causes the liver to move inferiorly over the pancreas, caudally displacing gas-filled bowel. Having the patient drink four 6-oz cups of degassed water can provide a sonographic window for improved visualization of the body and tail.

Normal Findings on Ultrasound

Three morphologic shapes of the pancreas have been described: tadpole shaped (44%), dumbbell shaped (33%), and sausage shaped (23%). Absolute measurements of pancreatic size are controversial, but the maximal normal anteroposterior

Figure 94-9 Normal pancreatic anatomy on ultrasound.

A. Transverse sonogram demonstrating the majority of the pancreas. The echogenicity of the pancreas (P) is greater than that of the liver (L). A, Aorta; I, inferior vena cava; arrow, superior mesenteric artery; asterisk, confluence of superior mesenteric vein and splenic vein. **B.** Transverse sonogram of a very echogenic pancreas due to fatty infiltration.

Figure 94-10 Uneven fatty replacement of the pancreas. Drawings illustrate the four different patterns of fatty replacement of the pancreas (green areas). The percentage of cases of uneven pancreatic lipomatosis represented by each type is also indicated. (From Mortelet KR, Rocher TC, Stretter JL, et al: Multimodality imaging of pancreatic and biliary congenital anomalies. *RadioGraphics* 26:715-731, 2006.)

diameters of the pancreatic head and body are 2.6 cm and 2.2 cm.⁵⁰ The tail is much more variable in shape and size and is not measured for diagnostic purposes. In a dumbbell-shaped pancreas, the tail may be 3.5 cm; when the pancreas is sausage shaped, the pancreatic head can be normal up to 3.5 cm.⁵¹ The pancreatic body is usually the narrowest part of the pancreas. In general, the pancreas is proportionately larger in young people; it decreases in relative size with age.^{52,53} The borders of the pancreas are usually smooth in youth and become somewhat irregular with age. Analysis of the shape of the uncinate process is particularly important because any rounding or enlargement implies disease.^{50,54}

The echogenicity of the pancreas is high throughout its substance. The pancreatic tissue texture or echo size is usually coarser, more inhomogeneous, and more echogenic than that of the liver (see Fig. 94-9). It is important to compare the echo patterns and amplitudes of the liver and pancreas at the same depth because dot size and echo amplitude are closely related to the transducer beam profile.^{55,56} The tissue texture of the pancreas is related to the extent of fatty infiltration.^{57,58} As the pancreas ages, it undergoes progressive fatty infiltration, and consequently it becomes more echogenic. Pancreatic parenchyma should be less echogenic than surrounding retroperitoneal fat. When the pancreas is completely replaced by fat in older individuals, it may be difficult to differentiate from the retroperitoneal fat.⁵⁹

Certain caveats apply in scanning the pancreas. Gas within the stomach and duodenum can cause subtle shadowing, artifactually decreasing the echogenicity of the adjacent pancreas.^{50,52} Different amounts of fat may be deposited in the

ventral (head and uncinate process) and dorsal (body and tail) pancreas, making the head appear hypoechoic. In some cases, demarcation of the different echogenicities can be seen to correspond to the expected fusion line of the dorsal and ventral embryologic moieties⁵³ (Fig. 94-10).

On occasion, prepancreatic fat between the stomach and pancreas can be prominent in some patients. It is usually somewhat less echogenic than pancreas and must be differentiated from fluid in the lesser sac, lymphadenopathy, and mural thickening of the stomach.^{60,61} The main pancreatic duct (duct of Wirsung) is identified sonographically in approximately two thirds of patients as an anechoic space surrounded by two parallel hypoechoic lines resembling trolley tracks.⁶² The maximal inner diameter is less than 2 mm; when it is larger, an obstructing mass, stricture, or stone must be suspected. The diameter of the pancreatic duct normally increases with age.⁶³⁻⁶⁷

A number of normal structures may simulate the pancreatic duct, so it is important to image the duct within the substance of the gland. The posterior wall of the stomach can mimic a dilated pancreatic duct, with normal pancreas dorsal and echogenic gastric lumen ventral, sandwiching the relatively hypoechoic gastric wall. The ingestion of water resolves this problem. A tortuous splenic artery can also simulate a dilated pancreatic duct or cystic pancreatic mass when it lies close to the pancreatic parenchyma. Doppler examination can easily resolve the confusion.^{68,69}

In patients with suspected choledocholithiasis or biliary obstruction, every effort should be made to visualize the distal common bile duct. It often is not visualized because it lies posterior to the second portion of the duodenum, which may be

gas filled. This is especially true if the duct is scanned in the supine or left posterior oblique position. A superior method for visualizing the distal common bile duct sonographically is to scan the patient in an erect right posterior oblique position and to rely primarily on transverse rather than parasagittal images. The erect right posterior oblique position minimizes gas within the antrum and duodenum; the transverse scanning plane optimizes identification of the course of the intrapancreatic distal duct.^{70,71} The posterior superior pancreaticoduodenal vein can mimic the distal common bile duct; color Doppler examination can easily differentiate the two structures.⁷²⁻⁷⁷

Intraoperative Ultrasound

Intraoperative sonography is a time-consuming but accurate means of localizing small islet cell tumors of the pancreas. It can also be used to guide open biopsy and aspiration.⁷⁸⁻⁸² With the increased use of laparoscopic techniques, probes for use during this procedure have also been introduced.⁸³

Endoscopic Ultrasound

Ultrasound transducers have been modified so that they can be incorporated into the tip of flexible endoscopes. These transducers have the advantage of higher frequency and spatial resolution, which may be of use in diagnosing small pancreatic tumors, in demonstrating subtle pancreatitis, and in evaluating islet cell tumors preoperatively.⁸⁴⁻⁸⁶ The proximity of the stomach and duodenum to the pancreas allows high-resolution imaging of the pancreas and eliminates the limits of overlying

bowel gas seen in transabdominal ultrasound. When indicated, pancreatic biopsies can also be performed by endoscopic ultrasound.

COMPUTED TOMOGRAPHY

CT is the best single technique for the noninvasive imaging of the pancreas. It is unaffected by bowel gas or large body habitus, is widely available, and is relatively easily performed. CT has greatly diminished the need for diagnostic ERCP and angiography.⁸⁷⁻⁸⁹ Multidetector CT techniques have improved CT examination of the pancreas, allowing thinner contiguous images, overlapping images without increased radiation exposure, and freedom from respiratory misregistration. The rapidity of scanning allows several acquisitions to be made through the pancreas during different phases of a single bolus of contrast material.⁹⁰⁻¹⁰⁸

Size, Shape, and Density on Computed Tomography

The morphologic appearance of the pancreas on CT depends on the amount of fat within the intralobular septa that separates the acinar lobules of the gland. In younger patients, the contour of the gland is smooth; the parenchyma is homogeneous, with an attenuation similar to that of spleen and muscle but less than that of liver on noncontrast scans (Fig. 94-11). With age and progressive fatty deposition, the pancreas becomes lobulated, irregular, and inhomogeneous.^{90,109}

Figure 94-11 Normal pancreas on CT. Because of the oblique line of the pancreas, the entire organ is seldom seen on a single image. **A.** Image through the body (B) and tail (T) of the pancreas. The splenic vein (arrow), which lies immediately dorsal to the body of the pancreas, is an excellent landmark. A, Aorta; D, duodenum; S, stomach; V, inferior vena cava. **B.** Image from the same patient obtained 1 cm caudal to **A** demonstrates the uncinus process of the pancreas. The superior mesenteric vein (arrow) is difficult to visualize on this image that was obtained early in the administration of the contrast material bolus. However, the arterial anatomy is well demonstrated. Curved arrow, Dorsal pancreatic artery. **C.** Coronal curved multiplanar reconstruction image of the pancreas demonstrates a small, side branch, intraductal papillary mucinous neoplasm (curved arrow). This technique is useful in imaging of the pancreatic duct in one image (straight arrows); asterisk, common bile duct.

Although the size of the pancreatic head, neck, body, and tail generally correspond to normal measurements found sonographically, absolute numbers should not be used alone in diagnosing pancreatic enlargement. It is important to observe symmetry within the gland, with the head (maximal normal diameter of 3 cm) being slightly larger in anterior-posterior dimension than the body (2.2 cm) and tail (2.8 cm). The pancreatic tail can be bulbous in some normal patients and measure larger than the head. The thickness of the head of the pancreas should be less than the transverse diameter of the adjacent vertebral body; the body and tail should be less than two thirds of the size. The pancreatic body may be thinner where it crosses the spine. The lateral contour of the pancreatic head may have discrete lobulations lateral to the gastroduodenal or anterior superior pancreaticoduodenal artery in approximately one third of normal examinations.¹¹⁰ The uncinate process has a triangular appearance on cross section as it projects behind the mesenteric vessels.¹¹¹⁻¹¹³ The pancreas moves an average of 3.2 cm craniocaudally between phases of respiration on CT scans.¹¹⁴

In patients with a surgically or congenitally absent left kidney, the pancreatic tail lies dorsomedial, adjacent to the spine, and occupies the empty renal fossa along with bowel and spleen. The entire pancreas may rarely lie to the left of the aorta.

The pancreatic vascular anatomy is well demonstrated by multidetector CT. The thinner slices and overlapping reconstructions allowed by helical technique visualize many of the small named vessels. The splenic vein makes an excellent landmark for the body and tail of the pancreas. The anterior and posterior superior pancreaticoduodenal veins are seen on 98% and 88% of scans, and the gastocolic trunk may be visualized on 89% of scans.¹¹⁵ Frequently visualized are the gastroduodenal, anterior and posterior superior pancreaticoduodenal, and right gastroepiploic arteries. Occasionally visualized are the dorsal pancreatic, pancreatica magna, and anterior and posterior inferior pancreaticoduodenal arteries.¹¹⁶

Pancreatic Duct on Computed Tomography

The normal pancreatic duct appears as a thin, tubular region of low attenuation coursing in the center of the pancreas on CT scans. The duct can be seen at least partially in 70% of normal

patients; usually, short segments are visualized on a limited number of scans. The duct is most frequently seen in the region of the pancreatic body as it arches over the spine and mesenteric vessels or in the region of the head.¹¹⁷

The normal pancreatic duct should be no wider than 2 to 3 mm, but it can occasionally be larger in older individuals. The normal fat plane between the splenic vein and pancreatic parenchyma should not be mistaken for the pancreatic duct.¹¹⁸

Common Bile Duct on Computed Tomography

The internal diameter of the distal common bile duct is less than 6 to 7 mm. In older patients or those with a history of previous biliary tract disease or surgery, the duct may be as large as 10 mm in the absence of obstruction. Thus, the diagnostic significance of ducts 7 to 10 mm in size is often difficult to assess.¹¹⁹ On contrast scans, the vasa vasorum of the duct may enhance.

MAGNETIC RESONANCE IMAGING

The pancreas had been one of the most difficult organs to image reliably on MRI until the development of techniques such as breath-hold imaging, chemically selective fat saturation, and dynamic gadolinium enhancement.¹²⁰ Now the routine use of fast sequences including three-dimensional gradient-echo T1-weighted and MR cholangiopancreatography (MRCP) sequences has resulted in excellent diagnostic quality when MRI is used as a problem-solving tool in patients with elevated liver function test results, acute pancreatitis, and pancreatic cancer. It is used as the primary imaging modality for suspected pancreaticobiliary pain, staging of chronic pancreatitis, and diagnosis and follow-up of cystic pancreatic tumors. The inability to demonstrate small calcifications remains a relative drawback.¹²¹

Normal Pancreas on Magnetic Resonance Imaging

On MRI studies (Figs. 94-12 and 94-13), the pancreas can appear smooth or lobulated and may blend in with the surrounding retroperitoneal fat if there is fatty infiltration.¹²²⁻¹³⁰ The pancreas may be isointense to slightly hyperintense compared with the liver on T1-weighted spin-echo sequences, isointense or slightly hyperintense on T1-weighted spoiled gradient-echo sequences, and slightly brighter on T2-weighted

Figure 94-12 Normal pancreatic anatomy on MRI T1-weighted images. **A.** T1-weighted out-of-phase gradient-echo image (239/2.4/70) shows the normal appearance of the pancreatic body (arrow) and tail (curved arrow). **B.** T1-weighted in-phase gradient-echo image (239/4.76/70) similarly shows the pancreas (arrow) without the chemical shift artifact. B, bowel; K, kidney; L, liver; S, spleen.

Figure 94-13 Normal MR images of the pancreas before and after gadolinium administration. **A.** T1-weighted fat-saturated breath-hold spoiled gradient-echo image (3.99/1.93/10) before the administration of contrast material demonstrates the normal high signal of the pancreas relative to the rest of the parenchymal organs (arrow) due to proteinaceous material within the glandular elements of the pancreas. This sequence is often the single best noncontrast sequence with which to evaluate the pancreas. **B.** T1-weighted postcontrast imaging with the same parameters shows an early phase of enhancement of the pancreas. Postcontrast images are routinely obtained at 60, 90, and 120 seconds after the administration of gadolinium.

Figure 94-14 Normal MRCP. **A.** Coronal thin-section 3-mm T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) image (1200/92/154) shows the common duct (arrow) and the pancreatic duct (arrowhead). Nondilated duodenum is also seen (curved arrow). **B.** Axial thin-section 3-mm T2-weighted HASTE image (1300/900/120) shows the normal appearance of the pancreatic body and tail (arrow). A nondilated pancreatic duct is partially visualized (arrowhead). **C.** Coronal thick-slab rapid acquisition and relaxation enhancement (RARE) image (3000/735/180) shows the common bile duct (arrow) and pancreatic duct (arrowhead). There is the suggestion of pancreatic divisum on this image. Filling defects in the gallbladder are compatible with gallstones. Gallbladder wall thickening is also present. **D.** Maximum intensity projection T2-weighted navigator sequence (3517/696/120) is able to locate the position of the diaphragm and thus correct for diaphragmatic motion to minimize respiratory motion and artifact. This maximum intensity projection image nicely displays the common bile duct (arrow) and pancreatic duct (arrowhead). Gallstones are again noted in the gallbladder lumen, and the presence of pancreatic divisum is confirmed on this image.

images. It is relatively high in signal on T1-weighted fat-saturated sequences and enhances rapidly with gadolinium administration. The normal pancreatic duct is occasionally visualized, particularly when torso coils are used. On axial T2-weighted images, the common bile duct can be seen as a bright dot in the pancreatic head, and the gastroduodenal artery appears as a rounded, black structure as a result of flow void phenomena.^{90,130}

MAGNETIC RESONANCE CHOLANGIOPANCREATOGRAPHY

An important technique to examine the pancreatic and biliary tree is MRCP.^{131,132} The normal and abnormal pancreatic duct can be visualized without the invasiveness of ERCP¹³³ (Fig. 94-14). Several variations of the technique have emerged.¹³⁴⁻¹³⁶ All have in common a heavily T2-weighted pulse sequence in

Figure 94-15 Normal diffusion-weighted MR image of the pancreas. **A.** Axial diffusion weighting ($b = 500 \text{ s/mm}^2$) shows normal homogeneous bright signal of the pancreas (arrow). **B.** Axial apparent diffusion coefficient map shows the normal appearance of the pancreas (arrow). The pancreas is homogeneous, and there are no areas of restricted diffusion.

which the fluid-filled ducts stand out from the surrounding low signal intensity tissues.¹³⁷ Many of these are breath-hold sequences that can easily be added to routine pancreatic imaging with little increase in overall examination time. Postprocessing with a maximum intensity profile technique allows visualization from multiple perspectives, giving an appearance similar to that of ERCP. Secretin administered before the dynamic acquisition of images has been used to improve visualization of the pancreatic duct, to diagnose papillary stenosis or dysfunction, and to evaluate reduced pancreatic exocrine reserve.¹³⁸ MRCP may be particularly valuable in postoperative patients in whom ERCP is technically impossible. This technique is discussed more fully in Chapter 75.

Diffusion-Weighted Magnetic Resonance Imaging of the Pancreas

Diffusion-weighted MRI of the pancreas is an emerging technique that is complementary to conventional MRI (Fig. 94-15). Diffusion-weighted MRI uses the differences in the motion of water molecules in extracellular and intracellular fluid and vascular fluids to produce image contrast. Restricted diffusion is observed in tissues with high cellularity, such as tumors, abscesses, and fibrosis. Unimpeded diffusion is found in tissues with low cellularity or disrupted cell membranes, such as cysts and necrotic tissues. Tissues with restricted diffusion will demonstrate hyperintensity on higher b values and hypointensity on the corresponding calculated apparent diffusion coefficient map. Diffusion-weighted MRI has been shown to be highly sensitive and specific for the detection of pancreatic adenocarcinoma and may be useful in detecting small or non-contour-deforming adenocarcinomas. Diffusion-weighted MRI is also useful to improve detection of liver and peritoneal metastatic lesions, which may provide more accurate staging in pancreatic cancer. The inability to differentiate mass-forming pancreatitis from poorly differentiated adenocarcinomas and to distinguish non-neoplastic cysts from cystic neoplasms remains a challenge. Diffusion-weighted MRI of the abdomen is further discussed in Chapter 69.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

ERCP affords opacification of both the pancreatic and the bile ducts. In addition, the endoscopist can inspect and perform a biopsy of suspicious periampullary lesions, perform a sphincterotomy with or without stone extraction, and place internal biliary stents.¹³⁹⁻¹⁴² A more complete discussion of ERCP can

be found in Chapter 74. The indications for ERCP include the following: to determine the cause of idiopathic pancreatitis (i.e., pancreas divisum); to provide a road map for the surgeon in patients with dilated ducts and chronic pancreatitis before the Puestow procedure; to identify communication of the pancreatic duct with pseudocysts and fistulas; to detect small intraductal pancreatic neoplasms that distort ductal anatomy but do not yet cause a mass effect that can be detected by CT and ultrasound; and to identify the cause of extrahepatic biliary obstruction (e.g., stone, tumor, benign stricture, or inflammation).¹⁴³⁻¹⁴⁵

The upper limits of normal pancreatic duct diameter on ERCP are 6.5, 5.0, and 3.0 mm for the head, body, and tail, respectively. The normal duct gently tapers from the major papilla to its origin in the pancreatic tail. Slight narrowing of the pancreatic duct can be seen at the junction of the ducts of Wirsung and Santorini and at the point at which the superior mesenteric artery crosses ventral to the pancreas. Normally, 20 to 30 side branches of the pancreatic duct, which measure 0.2 mm in diameter, are filled. The duct of Santorini is opacified in about 50% of pancreatograms. A patent accessory duct orifice is present in one third to two thirds of patients but is difficult to cannulate. With aging, the diameter of the pancreatic duct increases, the number of side branches filled decreases, and cystic dilation of the side branches may occur. The pancreatic duct moves significantly with various phases of respiration, particularly within the tail. Contrast material empties from the normal pancreatic duct in 2 to 7 minutes, but this figure increases in elderly patients to 10 minutes.

Injection of contrast material should be performed under fluoroscopic guidance at a pressure insufficient to cause parenchymal filling (acinarization). Injection should be terminated when acinarization occurs, if a pseudocyst is filled, if the patient complains of severe pain, or if contrast material is seen entering the duodenal lumen or wall. When a stricture or abrupt termination of the duct is encountered, heroic attempts to fill the duct upstream should be avoided. Spot films are obtained in the prone and oblique positions. On occasion, lateral and supine views may be needed to complete the examination and to fill the duct in the tail. Pancreatic emptying should be evaluated in this position as well.¹⁴⁶

Positron emission tomography/computed tomography (PET/CT) shows great promise in the staging of pancreatic carcinoma.¹⁴⁷⁻¹⁵⁴ The applications of PET/CT in pancreatic and other abdominal malignant neoplasms are discussed in Chapter 68.

Outcome

Conclusions

Historically, percutaneous biopsy has played only a limited role in the evaluation and management of pancreatic masses.¹ In the past, percutaneous biopsy was reserved mostly for tissue confirmation in tumors that appeared unresectable at the time of diagnosis, for diagnosis of lymphoma or metastatic disease (in which surgery typically would be unnecessary), and for differentiation of inflammatory pseudotumors from true pancreatic neoplasms.² In recent years, however, advanced multidetector computed tomography (MDCT) and magnetic resonance imaging (MRI) techniques have improved the detection of cystic pancreatic neoplasms, and as a result, the role of percutaneous pancreatic mass biopsy has steadily increased.^{3,4}

Similarly, although the mainstay for treatment of patients with acute necrotizing pancreatitis has traditionally been surgical débridement, percutaneous image-guided catheter drainage has been proposed as a safe and alternative treatment option.⁵ Many patients with pancreatic necrosis undergo fine-needle aspiration to differentiate between infected and sterile pancreatic necrosis and, if deemed necessary to control systemic toxicity, percutaneous image-guided catheter drainage of pancreatic necrosis.⁶

In this chapter, we review the specific clinical indications for pancreatic mass biopsy, summarize the reported diagnostic

efficacy of percutaneous pancreatic mass biopsy, discuss the technical factors that contribute to results and failures, and highlight the possible limitations and complications of this procedure. Finally, we emphasize the current status of therapeutic radiology in patients with complicated pancreatitis so that the practicing radiologist can understand the current role of percutaneous image-guided aspiration and catheter drainage in the diagnosis and management of patients with necrotizing pancreatitis and pancreatic pseudocysts.

Role of Interventional Radiology in the Management of Pancreatic Neoplasms

BACKGROUND

Pancreatic ductal adenocarcinoma, accounting for approximately 85% of all pancreatic neoplasms, is the fourth leading cause of cancer-related deaths in the United States; approximately 28,000 new cases of pancreatic cancer are diagnosed each year.^{7,8} Percutaneous biopsy is performed typically to diagnose the cause of a pancreatic mass identified by CT scan, MRI, or sonography.⁹ Biopsy is useful both to diagnose malignant disease and to determine the type of malignant neoplasm.¹⁰ For example, among malignant pancreatic tumors, including ductal adenocarcinomas, islet cell carcinomas, and lymphomas, each carries a different prognosis and is treated differently.

Percutaneous image-guided biopsy is an established means of diagnosing the cause of pancreatic masses.^{8,11,12} The procedure may be performed on an outpatient basis, and complication rates are low, ranging from 3% to 6.7%.^{13,14} A diagnostic rate of 97.7% was recently reported for CT-guided fine-needle aspiration biopsy of pancreatic masses.¹⁵ Endoscopic sonography-guided fine-needle aspiration biopsy is an increasingly used alternative technique for pancreatic mass biopsy.¹⁶

INDICATIONS FOR PANCREATIC MASS BIOPSY

Patients with Imaging Findings That Suggest Unresectable Pancreatic Cancer

Percutaneous pancreatic mass biopsy is mainly indicated in patients with no known malignant neoplasm but whose imaging findings suggest an unresectable pancreatic tumor.¹³ In these patients, biopsy provides a tissue diagnosis that allows appropriate nonsurgical treatment to ensue (Fig. 95-1). Important to realize is that in patients with unresectable pancreatic cancer and other extrapancreatic lesions, such as hepatic or peritoneal/omental masses, biopsy of the extrapancreatic mass could potentially result in less morbidity than biopsy of the pancreatic tumor. For example, in a patient presenting with both a

Figure 95-2 Percutaneous biopsy of pancreatic lymphoma. **A.** Axial T2-weighted MR image shows hyperintense mass (arrow) in the head of the pancreas with associated ductal dilation. Also note extensive portocaval and retrocaval lymphadenopathy. **B.** Axial noncontrast CT image (patient in prone position) shows needle sampling (25 gauge through 20 gauge) of pancreatic mass by coaxial technique and a posterior approach; cytology revealed pancreatic lymphoma.

pancreatic mass and a hepatic mass, if biopsy of the hepatic mass revealed a metastasis of pancreatic cancer, it would obviate subsequent biopsy of the pancreatic mass.

Patients with a Known Extrapancreatic Primary Cancer

Another indication for percutaneous biopsy of a pancreatic mass is in a patient with a pancreatic mass and a known extrapancreatic primary malignant neoplasm.¹⁷ Percutaneous pancreatic mass biopsy is indicated in these patients to differentiate a surgically resectable pancreatic ductal adenocarcinoma from a metastasis. A pretreatment diagnosis is needed because virtually all metastases are treated medically, whereas resectable pancreatic carcinomas are treated surgically.¹⁸ The importance of a pretreatment tissue diagnosis in these patients is especially emphasized in patients with lymphoma, renal cell carcinoma, and lung cancer, three tumors that spread not uncommonly to the pancreas.¹⁹ Therefore, when a pancreatic mass is detected in a patient with an extrapancreatic primary malignant neoplasm, the mass should not be presumed to represent a metastasis; biopsy should be performed (Fig. 95-2).

Patients with a Pancreatic Mass That May Be Caused by Inflammation

Chronic pancreatitis (including autoimmune and groove pancreatitis subtypes) can appear masslike and mimic a pancreatic

neoplasm.²⁰ Therefore, an inflammatory etiology should be considered to prevent a patient with a benign mass from going to surgery unnecessarily. Prior history and signs and symptoms of chronic pancreatitis are usually present. However, not infrequently, a pancreatic neoplasm with postobstructive pancreatitis induces overlapping symptoms. Therefore, if there is still the possibility of an inflammatory cause after a careful history and laboratory evaluation, percutaneous biopsy can be used to confirm the diagnosis of cancer or to identify an inflammatory cause.²¹

Patients with a Cystic Pancreatic Mass

The precise role of percutaneous biopsy in the evaluation of cystic pancreatic masses is still controversial.²²⁻²⁵ In the past, the majority of these masses have been considered “surgical lesions” because, with the exception of the benign serous microcystic pancreatic adenoma, cystic neoplasms typically are malignant or have malignant potential (mucinous cystic tumors, intraductal papillary mucinous neoplasm, solid pseudopapillary tumor of the pancreas); they cannot be characterized confidently as benign on the basis of imaging alone, and they can be diagnosed as benign with certainty only if they are removed completely and examined fully at pathology.²⁶ As a result, biopsy specimens obtained from the cyst’s wall or fluid typically contain only scant epithelial cells, inflammatory cells, and fibrous tissue, material that cannot be used to render a specific

Figure 95-3 Percutaneous biopsy of cystic pancreatic neoplasm. **A.** Axial T2-weighted MR image shows hyperintense cystic mass (arrow) in the body of the pancreas with surrounding rim of calcifications. **B.** Axial noncontrast CT image shows needle sampling (22 gauge) of pancreatic mass through a transhepatic approach; cytology and subsequent fluid analysis plus molecular marking revealed benign mucinous cystic tumor with indolent cytogenetics.

benign diagnosis. Retrieval of no malignant cells still leaves the interventional radiologist, referring physician, and patient with the possibility that the lesion was improperly sampled or missed.^{27,28}

Recently, helped by important advances in cyst fluid tumor marker analysis, immunohistochemistry, and molecular techniques, some authors have argued that percutaneous biopsy can be helpful in identifying patients with benign subtypes of cystic pancreatic masses, obviating surgery in these patients.^{27,29,30} Indeed, new advanced MDCT and MRI techniques have dramatically increased the detection of cystic pancreatic neoplasms, and although resection of all pancreatic cystic tumors would ensure that cancers are not missed, most small cystic pancreatic neoplasms grow slowly or not at all,^{3,4} and up to 87% of patients would undergo surgery unnecessarily.⁴ As a result, percutaneous biopsy may be advocated in selected circumstances, such as in symptomatic patients who have cystic pancreatic neoplasms smaller than 3 cm, patients who have comorbidities that increase the risk of surgical exploration, and patients with a cystic pancreatic mass diagnosed in the setting of acute or chronic pancreatitis (Fig. 95-3). In these patients, biopsy results can simply serve as additional data that can be combined with imaging data to render a probable clinical diagnosis.

Multiple Solid Pancreatic Masses

As pancreatic ductal adenocarcinoma is solitary in more than 95% of cases, patients without a known primary malignant neoplasm who present with multiple, solid pancreatic masses are also good candidates for pancreatic biopsy.²⁶ The differential diagnosis includes metastatic disease, but this is not likely if a primary tumor is not known. Primary lymphoma is another possibility, although lymphoma more commonly involves the pancreas secondarily, and associated lymphadenopathy is usually present at time of presentation. Other differential diagnostic possibilities include multifocal nonhyperfunctioning endocrine tumors and multifocal solid-appearing microcystic pancreatic adenomas. A diagnosis of lymphoma or multifocal solid-appearing microcystic pancreatic adenomas would lead to medical treatment (Fig. 95-4). A diagnosis of multifocal nonhyperfunctioning endocrine tumors would allow the surgical treatment of each tumor to be planned such that the maximum amount of functioning pancreatic tissue can be left remaining.

TECHNICAL CONSIDERATIONS

Percutaneous biopsy of pancreatic masses is now most often guided by ultrasound, CT, and, rarely, MRI. To our knowledge, there are no data to support use of one modality for all masses.^{31,32} Ultrasound is widely available, multiplanar, portable, and free of ionizing radiation; it provides real-time imaging and is less expensive than CT or MRI. However, not all pancreatic masses are visible with ultrasound. Because of its posterior location in the anterior pararenal space, the pancreas cannot always be seen in patients with intervening bowel gas or excessive abdominal fat, and it may be difficult to visualize the location of the needle tip.³¹ CT can be used to visualize almost all pancreatic masses (although intravenous contrast material may be needed rarely) and is excellent in depicting surrounding normal pancreas, the hypodense/hypovascular tumor, and the needle tip.³² MRI is typically reserved for the unusual mass that is not visualized well with CT or ultrasound. In general, we recommend using the imaging modality that depicts the mass best and that modality with which the radiologist is most familiar.

Percutaneous biopsy of pancreatic masses can be performed with a wide range of needle sizes.³³ Percutaneous pancreatic mass biopsy refers to a procedure during which imaging is used to guide any needle into a pancreatic mass percutaneously for the purpose of obtaining a tissue diagnosis.³³ This includes biopsies that use fine needles (20 gauge or thinner) or large needles (19 gauge or larger). Some authors distinguish between fine-needle aspirations, during which only fine needles are used and the tissue is examined cytologically, and biopsies, during which large needles are used to procure fragments of tissue, sometimes referred to as cores, which are examined histologically.³³ In general, fine-needle aspiration biopsy specimens are analyzed cytologically, and large-needle biopsy specimens are analyzed histologically. Needles may also differ by type; some are end cutting, others are side cutting.

There are no data to suggest that pancreatic masses are better biopsied with fine needles (20 gauge or thinner) or large needles (19 gauge or larger). Diagnostic sensitivities for percutaneous biopsy procedures using only fine needles vary from 71% to 94.7%.³⁴⁻³⁶ The reason for this range of diagnostic sensitivity might be that some studies included cystic and solid pancreatic masses, whereas others focused on solid pancreatic masses only. As mentioned before, the diagnostic work-up of most cystic

Figure 95-4 Percutaneous biopsy of multiple pancreatic masses. **A.** Coronal contrast-enhanced CT image shows two heterogeneous masses (arrows) in the head and tail of the pancreas. **B.** Axial noncontrast CT image shows large-needle sampling (18-gauge side-cutting device) of pancreatic mass in the tail. **C.** Axial noncontrast CT image shows fine-needle sampling (22 gauge) of pancreatic mass in the head; cytology and surgical pathology assessment of both masses revealed serous microcystic pancreatic adenoma. **D.** Axial noncontrast CT image shows small retroperitoneal hemorrhage (arrow) around the pancreatic tail that was self-limited.

pancreatic masses involves analysis of cystic fluid for biochemical and tumor markers rather than tissue sampling; thus, the accuracy of fine-needle aspiration biopsy is related to both the ability to position a needle in a mass and the accuracy of the biochemical analysis of the cystic fluid.²⁸

Biopsies performed with large (typically 18 gauge) needles have yielded similar sensitivities.^{37,38} These series showed that sensitivities for detection of malignant neoplasms range from 69% to 93%. Therefore, although there has been no statistically valid comparison study for any definitive conclusions to be drawn, on the basis of current available data, it is reasonable to conclude that fine needles are adequate by themselves to biopsy the majority of pancreatic masses. Although use of large needles may increase accuracy in selected circumstances, we believe that they increase the risk of complications, particularly bleeding and pancreatitis. Therefore, in our practice, we begin with fine needles and ask our cytologists to examine one or two specimens intraprocedurally. If the preliminary cytology impression is that the specimen is adequate, the procedure is completed with fine needles alone. If there is any question as to the specimen's adequacy, we obtain large-needle specimens for histologic analysis.³³

The pancreas is located in the anterior pararenal space, and access routes that avoid traversal of liver, stomach, colon, small bowel, spleen, or kidney are preferentially selected to minimize the risk of bacterial contamination and hemorrhage. If possible, an approach avoiding traversal of normal pancreatic tissue is also preferred to minimize the risk of pancreatitis. Anterior routes through the liver or stomach can be used if no other routes are available. Transgressing the stomach theoretically increases the risk of infection in patients who are receiving H1 receptor blockers or any other medications that raise gastric pH

because the gastric fluid is not sterile. Moreover, percutaneous biopsy of cystic pancreatic lesions by a transgastric route may impair the diagnostic accuracy of the biopsy because gastric mucin-producing cells may contaminate the smear.

DIAGNOSTIC EFFECTIVENESS

Several studies have evaluated the sensitivity, specificity, and overall accuracy of biopsy of pancreatic masses. These studies vary considerably with respect to patient population, tumor type, guidance modalities, and needle size.¹⁵ Overall, the sensitivity of biopsy for diagnosis of malignant disease is 71% to 97% regardless of needle size used or whether the specimens were examined by cytology, histology, or both.¹⁵ False-negative results are most often due to failure to place the needle tip accurately in a small mass or to sampling of coexistent desmoplastic reaction or pancreatitis adjacent to the mass. Even in experienced hands, false negatives do occur, suggesting that negative results should be viewed with caution in patients with a radiologically suspicious mass.

Tillou and associates¹³ reported a diagnostic rate of 96.5% for diagnosis of pancreatic masses by CT- and transabdominal ultrasound-guided fine-needle aspiration biopsy. In a retrospective study, Qian and Hecht³⁶ showed that CT-guided biopsies had sensitivity of 71%. In the study by Mallery and coworkers,⁹ CT- and transabdominal ultrasound-guided pancreatic biopsies (80%) had a higher sensitivity than endoscopic sonography-guided biopsies (74%). In one study, we also found higher sensitivity for CT guidance (94.9%) compared with endoscopic sonographic guidance (85%).¹⁵ However, the difference did not reach statistical significance. In the study of Qian and Hecht,³⁶ the negative predictive values of CT- and

endoscopic sonography-guided fine-needle aspiration biopsies were similar, 41% and 45%, respectively. Mallery and coworkers⁹ reported negative predictive values of 23% and 27% for fine-needle aspiration biopsies performed under CT and endoscopic sonographic guidance, respectively. We found negative predictive values of 60% and 57.1% for CT- and endoscopic sonography-guided fine-needle aspiration biopsy, respectively. Also in our study, the frequency of small masses biopsied under endoscopic sonographic guidance (81.5%) was significantly higher than the frequency of those biopsied under CT guidance (32.6%).¹⁵ In fact, since the first report of the use of endoscopic sonography-guided fine-needle aspiration biopsy for the diagnosis of pancreatic cancer in 1994,³⁹ it has been reported that endoscopic sonography-guided fine-needle aspiration biopsy is more accurate than CT-guided fine-needle aspiration biopsy, especially for small pancreatic masses.³⁴ To evaluate the effect of mass size on biopsy performance, we stratified results by mass size. There were no significant differences in test characteristics between the guidance groups after the data were stratified by mass size; small masses were not more effectively biopsied under endoscopic sonography guidance.¹⁵

Because cytology is a relatively insensitive test in the diagnosis of cystic pancreatic neoplasms, advances in cyst fluid tumor markers analysis, immunohistochemistry, and molecular techniques have been used to improve the sensitivity for detection of malignant changes in these lesions. Cyst fluid carcinoembryonic antigen (CEA) values are uniformly low in serous pancreatic adenomas, higher in mucinous lesions, and markedly elevated in mucinous cystadenocarcinomas.²⁷ A pooled analysis of 12 studies in 450 patients on the role of cyst fluid analysis in the differential diagnosis of pancreatic cystic lesions showed that a CEA level greater than 800 ng/mL is strongly suggestive of a mucinous tumor.⁴⁰ Other studies confirmed that of all tested markers (e.g., amylase, mucicarmine staining, carbohydrate antigen 19-9), cyst fluid CEA is the most accurate test available for the diagnosis of mucinous cystic lesions of the pancreas.⁴¹⁻⁴³ Finally, studies have revealed specific roles of molecular analysis of clusterin- β and *MUC4* to help distinguish reactive ductal epithelial cells from the cells of pancreatic adenocarcinoma in fine-needle aspiration samples,⁴⁴ of mutational analysis for *K-ras* point mutations and loss of heterozygosity in differentiating benign from malignant cystic neoplasms,³⁰ and of immunohistochemical staining for *MUC1* overexpression as a specific marker of invasive carcinoma in intraductal papillary mucinous neoplasm.²⁹

COMPLICATIONS

Percutaneous pancreatic mass biopsy is a safe procedure, and reported complication rates are low for both CT-guided and sonography-guided fine-needle aspiration biopsy of the pancreas.¹⁵ In a meta-analysis, Chen and associates¹⁸ reported a complication rate of 4% for CT-guided procedures. Bleeding is the most frequent complication, but it is usually subclinical, detected only with a postprocedural CT scan, and self-limited because of the retroperitoneal location of the pancreas. Although there are no direct comparison data, we believe that peripancreatic hemorrhage is more likely with large needles.

The second most common complication is acute pancreatitis due to inadvertent transgression or biopsy of normal pancreatic parenchyma. It is almost always self-limited but may be prolonged because of pancreatic ductal disruption.⁴⁵

Seeding of the needle track with tumor is a theoretical consequence of percutaneous biopsy of a malignant pancreatic mass, but it is extremely rare and therefore should not be a deterrent to biopsy when there is an appropriate indication. To our knowledge, only one case of needle track seeding associated with pancreatic mass biopsies has been reported.⁴⁶

Role of Interventional Radiology in the Management of Acute Necrotizing Pancreatitis

BACKGROUND

The International Symposium on Acute Pancreatitis held in 1992 in Atlanta defined acute pancreatitis as inflammation of the pancreas with variable secondary involvement of remote organs.⁴⁷ Acute necrotizing pancreatitis is a severe form of the disease associated with significant morbidity and mortality. Percutaneous image-guided catheter drainage is an important treatment option that can be lifesaving when it is used alone or as an adjunct to surgery.⁵ Successful treatment outcomes depend on close cooperation and teamwork among gastroenterologists, surgeons, and interventional radiologists.⁵

Pancreatic necrosis is defined as a diffuse or focal area of nonviable pancreatic tissue.⁴⁸ Infection of the necrotic portion of the pancreas results in infected necrosis. Infected pancreatic necrosis is an "intermediate" complication of acute pancreatitis, usually occurring between the third and eighth weeks after onset of symptoms.⁴⁹ Infected necrosis and sterile necrosis both carry a high mortality rate.⁵ Mortality rates of 30% to 35% have been reported in patients with infected necrosis and 10% to 15% in patients with sterile necrosis.⁷ Although the presence of infection increases the mortality rate in patients with pancreatic necrosis, a review of 1110 cases of acute pancreatitis demonstrated that mortality is more strongly linked to the presence of organ failure than to the presence of infection itself.⁵⁰

Although no universally accepted treatment algorithm exists, a general consensus of indications for the interventional approach to patients with acute pancreatitis has been described.^{5,7,51-61} Some percutaneous drainage procedures are performed to stabilize the seriously ill patient before surgical débridement, whereas others are done with the intent to cure. In some cases, percutaneous drainage follows surgical therapy that has been only partially successful.⁶² Treatment algorithms vary among medical centers and are sometimes based on expertise of both the interventional radiologist and the surgeon. The clinical status of the patient, for instance, the presence of sepsis, also influences which approach is best in any given clinical situation.^{5,7}

IMAGE-GUIDED CATHETER DRAINAGE: TECHNIQUE

Access Route

Most pancreatic fluid collections are located in the lesser sac, the anterior pararenal space, or other parts of the retroperitoneum.⁴⁸ Access routes that avoid traversal of colon, small bowel, stomach, spleen, and kidney are preferred to minimize the risk of bacterial contamination and hemorrhage. If possible, a retroperitoneal approach through the lateral flank is chosen over an anterior approach through the peritoneum.⁷ Some authors

Figure 95-5 Percutaneous fine-needle aspiration of sterile necrotizing pancreatitis.

A. Axial contrast-enhanced CT image shows hypovascular area in the body of the pancreas consistent with pancreatic necrosis. **B.** Axial noncontrast CT image shows needle sampling (20 gauge) of pancreatic necrotic collection through a right anterior approach. The fluid was analyzed and found to be sterile.

suggest that anterior routes involve the theoretical disadvantage of antigravity flow of fluid through the catheter.^{5,7} Anterior routes through the liver or stomach can be used if no other routes are available.^{5,7} Transgressing the liver theoretically increases the risk of bleeding but in practice is generally safe. Transgressing the stomach is also safe, but peristalsis in the stomach may result in catheter dislodgment several days after its placement. Moreover, caution should be taken in patients who are receiving H1 receptor blockers or any other medications that raise gastric pH because the gastric fluid may not be sterile. Fluid collections involving the pancreatic tail can be drained through the left anterior pararenal space, avoiding the descending colon posteriorly.^{5,7} Similarly, pancreatic head collections can be drained through the right anterior pararenal space.⁶ Typically, the patient's position on the interventional CT table should be adjusted to a slight posterior oblique position to optimize access to the region of interest.

Catheter Selection and Placement

The fluid contained in collections caused by pancreatic necrosis is often viscous. Therefore, adequate drainage of pancreatic and peripancreatic collections typically requires catheters with multiple side holes and a minimum diameter of 12F to 14F.⁵²⁻⁶¹ Multiple catheters may be required to drain large or multiloculated necrotic collections. If the fluid is not viscous, 12F to 14F drainage catheters may be satisfactory.^{5,7} Either the tandem trocar technique or Seldinger technique can be used, depending on the operator's experience. If the Seldinger technique is used, the catheter track should be sequentially dilated over a guide-wire. If the necrotic material is viscous and the collection is not drained completely, catheters larger than 14F may be exchanged several days after a 14F catheter is placed initially. An attempt should be made to place as much length of the catheter containing side holes as possible transversely into the necrotic pancreatic collection from the lateral flank approach to maximize drainage.^{5,7}

MANAGEMENT OF STERILE PANCREATIC NECROSIS

In general, in patients with sterile pancreatic necrosis, CT scans of the abdomen are repeated every 7 to 10 days to follow the evolution of pancreatic necrosis and to look for complications.³ Patients who persistently show clinical instability with tachycardia, fever, leukocytosis, or organ failure may require image-guided percutaneous needle sampling to evaluate for infected pancreatic necrosis.⁵¹ It is important that the access route avoid

small and large bowel so as not to contaminate the collection or the aspiration sample^{5,7} (Fig. 95-5).

If sampled pancreatic fluid is sterile, the patient is considered to have sterile pancreatic necrosis. Some of these patients recover rapidly without additional intervention, whereas others remain persistently toxic because of pancreatic duct disruption with extravasation and accumulation of noxious pancreatic juice into peripancreatic spaces; they usually require continuous support in an intensive care unit.⁶³ Several years ago, patients with persistent toxicity underwent urgent surgical débridement; however, now these patients are managed nonsurgically because early surgical débridement contributes to morbidity and mortality.⁶³⁻⁶⁵ A combination of percutaneous catheter drainage and supportive care offers an alternative to surgery.⁵²

Some suggest that persistently toxic patients should undergo percutaneous image-guided needle sampling every 7 to 10 days to assess for infected necrosis.⁵¹ Instead of performing regular needle sampling, the necrotic fluid may be drained percutaneously.⁶⁶ One or more catheters may be placed and irrigated per standard radiologic protocol to provide a "radiologic necrosectomy" and to reduce systemic toxicity.⁶⁶ Percutaneous catheter drainage of sterile necrosis is, however, still controversial. Only one clinical study is currently available that has compared the results of therapy using weekly percutaneous needle sampling to assess for infection versus indwelling catheter drainage of sterile necrosis.⁶⁶

The main rationale for not using percutaneous catheter drainage is the potential of infecting a sterile pancreatic collection.⁶⁷ Although indwelling catheter colonization is common, serious clinical infection is unlikely to occur if all the fluid and material are drained within 2 or 3 days of the intervention.^{5,7,66} This requires vigilant attention to follow-up CT scans and placement of additional or larger catheters to drain the residual fluid. Adequate drainage is achieved when no residual necrotic fluid is present on follow-up CT scans.

MANAGEMENT OF INFECTED PANCREATIC NECROSIS

Although contrast-enhanced CT scan is excellent in assessing for pancreatic necrosis, it cannot distinguish between infected and sterile necrosis with certainty.⁴⁸ Intrapancreatic, retroperitoneal, or lesser sac gas is a rare finding on CT; however, if it is present, it typically indicates infection.⁴⁸ Bacterial infection of necrotic pancreatic tissue is common and associated with high morbidity and mortality. The risk of infection may or may not increase with the amount of pancreatic necrosis.⁵⁰

Infected pancreatic necrosis has traditionally been managed with surgical necrosectomy and antibiotics.⁶⁵ Percutaneous catheter drainage is often ineffective because of blockage of the catheter by necrotic tissue fragments and viscous fluid.⁶⁵ However, when patients are too unstable to undergo surgery, percutaneous catheter drainage may be successful in draining liquefied pus and minimizing the systemic manifestations of sepsis, thereby preparing patients for surgery.⁶⁸⁻⁷¹

Percutaneous catheter drainage may also be successful alone.⁶⁹ In a study of 23 patients with 38 infected pancreatic fluid collections who were drained percutaneously, 65% were cured without surgery and 35% required some type of surgical intervention after drainage.⁶⁹ Catheter drainage time averaged 29 days for patients with isolated collections and 96 days for patients with pancreatic duct fistulas.⁶⁹ Success largely depends on the following factors: all the collections must be drained; if they are persistent after 2 or 3 days of drainage, additional catheters should be placed and large-bore catheters are often required; vigorous bedside catheter irrigation should be done at least three times a day with 20 mL of sterile saline injected; and follow-up CT scans must be obtained frequently to assess for treatment response^{69,72} (Fig. 95-6).

COMPLICATIONS

Reported major complications of CT-guided catheter drainage are hemorrhage and injury to adjacent organs, such as bowel.^{5,7} Hemorrhage is uncommon and may be due to pancreatitis itself rather than to the drainage procedure^{5,7} (Fig. 95-7). After all percutaneous drainage procedures, CT scan of the abdomen should be done to assess for retroperitoneal hemorrhage. Venous bleeding is usually self-limited. Arterial

pseudoaneurysm or active arterial hemorrhage due to injury of adjacent vessels, such as the splenic artery, requires angiographic embolization. Fistulization to adjacent bowel is almost always due to the pancreatitis itself rather than to catheter drainage.^{5,7} Inadvertent insertion of the catheter through the bowel may occur when bowel loops are collapsed or unopacified. In most cases, the bowel heals without the need for surgical repair.^{5,7}

CATHETER CARE

Daily rounds should be performed by the interventional radiologist with assessment of the patient's vital signs, white blood cell count, and clinical status.⁷² Catheters should be irrigated with sterile saline at least three times a day with a technique that involves aspirating and discarding all the fluid that can be withdrawn from the catheter, followed by forward flushing into the abscess cavity with 20 mL of sterile saline.^{5,7} The process is repeated until the fluid is clear, typically two or three times. Finally, 10 mL of sterile saline is instilled into the catheter toward the patient and an additional 10 mL toward the bag to prevent catheter plugging. The stopcock between the catheter and the drainage bag connecting tube should be left in the open position. It is important to document accurate drainage output amounts by subtracting the instilled volume of saline from the total drainage volume. The nurses should be familiar with drainage catheters placed by interventional radiology so that flushes are done promptly.

Abdominal CT scans should be obtained periodically on the basis of the clinical status and amount of drainage to check for residual or undrained fluid collections.^{5,7} This helps determine whether drainage is adequate or additional catheters should be

Figure 95-6 Percutaneous catheter drainage of infected necrotizing pancreatitis. **A.** Axial contrast-enhanced CT image shows necrotic collection replacing the pancreatic gland. **B.** Axial CT fluoroscopic image obtained on the same day shows needle sampling (20 gauge) of pancreatic necrotic collection; purulent material was aspirated, and two drainage catheters were placed. **C.** Axial contrast-enhanced CT image obtained 14 days after the drainage procedure shows two percutaneous drainage catheters (14F and 18F) placed through the anterior approach and small residual collection.

A. Axial contrast-enhanced CT image (patient prone) shows well-defined fluid collection around the tail of the pancreas consistent with organized pancreatic necrosis. Note proximity of the collection to the spleen (arrow) and needle sampling (20 gauge) of pancreatic necrotic collection.

B. Axial nonenhanced CT image (patient prone) shows percutaneous drainage catheter (14F) placed through the intercostal approach. **C.** Axial noncontrast CT image obtained 5 days later shows large subcapsular splenic hematoma (arrows). **D.** Coronal contrast-enhanced CT image obtained 3 weeks later shows near-resolution and liquefaction of splenic hematoma (white arrows) and presence of percutaneous drainage catheter (black arrow).

placed. If a catheter is not draining and abdominal CT shows residual collection, the catheter may be blocked or the side holes may not be contiguous with the collection. In such cases, the catheter should be exchanged over a guidewire and repositioned appropriately within the collection or removed and a new catheter placed (Fig. 95-8).

Our criteria for catheter removal include no residual collection on a follow-up CT scan and catheter output of no more than 10 mL/day of nonpurulent fluid for 2 consecutive days. It is important not to remove the catheter solely on the basis of imaging results without assessing the amount of drainage.^{5,7} Likewise, it is important not to remove catheters solely because they stopped draining; catheters may become plugged or be pulled out from the collection. As a result, a CT scan will show residual fluid. In some cases, CT scan may show complete resolution of the collection; however, if there is communication with the pancreatic duct or its branches, the catheter may still be draining significant amounts of fluid daily.^{5,7} Similarly, catheter output may be scant, but a fistula may still be present. Pancreatic duct fistulas usually close over time if the collection is completely drained.⁷³

Patient communication and catheter education must be established as the catheters may have to remain in place for weeks to months.^{5,7} Once stabilized, patients can be discharged home with the catheter in situ and observed as outpatients.

Periodic visits with the interventional radiologist are scheduled for inspection of the catheter insertion site.

ANCILLARY PROCEDURES

Patients with acute pancreatitis may need additional supportive procedures performed by the interventional radiologist.⁵ These include image-guided thoracentesis and paracentesis, fluoroscopically guided nasojejunal or percutaneous jejunal feeding tube placement, and angiographic embolization of pseudoaneurysms or hemorrhaging vessels.^{5,7} Several studies support the use of enteral nutrition rather than parenteral nutrition in patients with acute pancreatitis.⁷⁴⁻⁷⁶ Therefore, nasojejunal or percutaneous jejunal feeding tube placement should be attempted whenever possible.

Some patients with sterile necrotizing pancreatitis remain toxic after 3 to 6 weeks. This is often due to one or more pancreatic duct disruptions with extravasation of noxious pancreatic juice.⁶⁶ Some reports advocate endoscopic placement of a stent across a disruption.^{77,78} However, there are several reasons not to recommend endoscopic pancreatic stent placement in the setting of sterile necrosis.⁵² First, the duct may be obstructed and disruption may not be visualized. Second, if there is no obstruction, the injected contrast material may extravasate and infect the necrotic area. Third, with extensive necrosis of the

Figure 95-8 Percutaneous drainage catheter dislodgment. **A.** Axial noncontrast CT image shows needle sampling (22 gauge) of pancreatic necrotic collection through an anterior approach. **B.** Axial noncontrast CT image shows percutaneous drainage catheter (14F) insertion by a tandem technique. **C.** Axial noncontrast CT image shows percutaneous drainage catheter in place and complete resolution of pancreatic fluid collection. **D.** Axial contrast-enhanced CT image obtained 14 days after the drainage procedure shows dislodgment of the catheter (arrow) and spillage of pancreatic fluid in the omentum and peripancreatic tissues.

body of the pancreas, the distal portion of the duct cannot be visualized or accessed by a stent. Fourth, even if a stent can be placed across a disruption, it may act as a foreign body and result in superinfection.

If a follow-up CT scan demonstrates complete resolution of the pancreatic collection but the catheter continues to drain significant amounts of fluid daily, there is communication with the pancreatic duct. Fluoroscopic abscessography is then used to visualize the communication and the appearance of the pancreatic duct.⁷³ This communication usually heals over time if the collection is drained completely.

Role of Interventional Radiology in the Management of Pancreatic Pseudocysts

INDICATIONS

Pseudocysts are collections of pancreatic juice enclosed by a wall of granulation tissue.⁷⁹ Typically, they require 4 weeks or more to evolve and result from acute pancreatic fluid collections. Less than 10% of patients with acute pancreatitis will develop pancreatic pseudocysts.⁸⁰ They vary in size and location and are usually asymptomatic. By imaging, pseudocysts are homogeneous fluid collections with attenuation of the fluid content less than 15 HU. The surrounding fibrous pseudocapsule is usually thin (<2 mm). Calcification of the wall, typically curvilinear in shape, is not uncommon. Chronic pseudocysts (i.e., those that do not resolve over time) may point to a persistent communication with the pancreatic duct or its side

branches.^{79,80} When symptomatic, pseudocysts are typically larger than 5 cm and older than 6 weeks. These symptomatic pseudocysts are usually amenable to percutaneous drainage; large nonsymptomatic pseudocysts usually do not need treatment.^{81,82} Secondary complications of pseudocyst formation include infection (resulting in a pancreatic abscess) and erosion into a vessel (resulting in a pseudoaneurysm).

A pancreatic abscess or infected pseudocyst is a circumscribed collection of pus containing little or no necrosis.⁸³ Its incidence is far less (3%) than that of infected pancreatic necrosis; it usually occurs later in the course of the disease, and it is typically multibacterial. Importantly, the mortality of pancreatic abscess is minimal. Among many reasons for this, one is that pancreatic abscesses are typically amenable to percutaneous catheter drainage⁸³ (Fig. 95-9). In most cases, imaging cannot be used to rule in or to rule out the presence of infection in patients with localized fluid collections. Therefore, image-guided percutaneous aspiration is frequently required for diagnosis.

OUTCOME

Percutaneous drainage is an effective frontline treatment for most pancreatic pseudocysts^{84,85}; cure is likely if fluid collections are drained adequately and if sufficient time is allowed for closure of fistulas from the pancreatic duct. In the largest series reported to date,⁸⁴ percutaneous drainage of 101 pancreatic pseudocysts (51 infected, 50 noninfected) in 77 patients is described. In this group of patients, 91 of 101 pseudocysts (90.1%) were cured by means of catheter drainage (noninfected, 43 of 50 [86%]; infected, 48 of 51 [94.1%]). Six patients

Figure 95-9 Percutaneous catheter drainage of infected pseudocyst (pancreatic abscess). **A.** Axial nonenhanced CT image shows well-defined fluid collection adjacent to the tail of the pancreas with peripheral calcifications consistent with pancreatic pseudocyst. The collection was needle sampled through a left anterior approach; the fluid was analyzed and found to be infected. **B.** Axial contrast-enhanced CT image obtained 3 weeks later shows complete resolution of the infected pseudocyst.

underwent operation after percutaneous treatment because of persistent drainage. In patients with infected pseudocysts, the infection was eradicated by percutaneous drainage before operation. Four pseudocysts recurred and were redrained percutaneously. The mean duration of drainage was 19.6 days (infected pseudocysts, 16.7 days; noninfected, 21.2 days). Four major complications (superinfection of sterile pseudocysts) and six minor complications occurred. Therefore, it can be concluded that percutaneous catheter drainage is a safe and valuable procedure in the management of patients with pancreatic pseudocysts.

Conclusions

Percutaneous biopsy of pancreatic masses is a safe and accurate procedure and can be used to diagnose malignant disease and to guide treatments. In the future, biopsy performance will undoubtedly improve as the field of cytology expands to include

a more sensitive and specific array of immunocytochemical reagents and cytogenetic markers that can be used to improve the analysis of percutaneous needle biopsy specimens.

Image-guided catheter drainage of fluid collections in and around the pancreas in patients with complicated pancreatitis is an important therapeutic option either alone or as an adjunct to surgery.⁸⁶ Successful percutaneous treatment of necrotic collections of the pancreas depends on several important factors. Typically, multiple large-bore catheters are required to drain large or multiloculated collections. Catheters often need to remain in place for several weeks and sometimes months, hence the need for close follow-up. Daily interventional radiology rounds, frequent vigorous bedside catheter irrigations, and willingness to place additional catheters for undrained collections are the norm in the care of these patients. Successful outcomes are best achieved when there is close cooperation among the interventional radiologist, gastroenterologist, and surgeon.

CHAPTER OUTLINE

Embryology

Variants of Normal Anatomy

Congenital Anomalies of the Pancreas

Pancreas Divisum

Annular and Semiannular Pancreas

Ectopic Pancreatic Tissue

Agenesis, Hypoplasia, and Hyperplasia of the Pancreas

Ductal Abnormalities

Congenital Cysts

To recognize the anatomic variants of the pancreas and to understand how various pancreatic anomalies develop, it is important to be familiar with pancreatic embryology and development. Errors or variations at several critical periods in the development of the pancreas are responsible for the majority of anomalies. These anomalies can vary in their presentation from being totally asymptomatic to being inconsistent with life.¹⁻⁵ In this chapter, a brief discussion of the important events of pancreatic embryology is followed by presentation of normal variants and various types of pancreatic anomalies.

Embryology

The pancreatic duct develops from two buds originating from the endodermal lining of the duodenum.⁶ One is the dorsal pancreatic bud, which is in the dorsal mesentery and is seen as a diverticulum of the foregut before 28 days. It grows into the dorsal mesentery (Fig. 96-1A). The other is the ventral pancreatic bud located close to the bile duct and appears as an invagination at the biliary-duodenal angle between 30 and 35 days.¹

The dorsal and ventral pancreatic buds soon grow into a pair of branching, arborized ductal systems, each with its own central duct (Fig. 96-1B). At day 37, the ventral pancreas rotates posterior to the duodenum and comes into contact with the dorsal pancreas (Fig. 96-1C). These two anlagen fuse and together with the duodenum fuse with the abdominal wall. In the mature organ, the ventral primordium becomes the inferior portion of the head and the uncinate process, and the dorsal pancreas becomes the body and tail. After the fusion, a new duct connects the distal portion of the dorsal pancreatic duct with the shorter duct of the ventral pancreas to form the main duct or the duct of Wirsung (Fig. 96-2). This main pancreatic duct, which is present in approximately 91% of adults, enters the duodenum together with the bile duct at the major papilla. The proximal portion of the dorsal pancreatic duct is pinched off during fusion and usually atrophies and disappears but may

persist as the small accessory duct of Santorini, which has a variety of appearances (Fig. 96-3). This accessory duct empties into the duodenum at the minor papilla 2 to 3 cm proximal to the ampulla of Vater.^{7,8} In about 10% of all cases, the duct system fails to fuse and the original double system persists.^{1,9}

As the duodenum grows and differentiates, the duodenal wall resorbs the distal bile duct up to its junction with the pancreatic duct. Different degrees of resorption account for variations in the appearance and relationships of the common bile duct and pancreatic duct. If ductal resorption is minimal, a long intramural ampulla is created, and the junction is extramural. The junction becomes intramural with increasing degrees of resorption, which produces a shortened ampulla.¹⁰⁻¹⁵ Maximal resorption produces separate orifices for the pancreatic duct and common bile duct (see Fig. 96-2), which no longer share a common ampulla.^{7,16}

Beginning in the third month of fetal life, the islets of Langerhans develop as clusters of cells from the terminal ductules. They become intimately associated with the capillary plexus and finally separate from the ductules to become the endocrine portion of the pancreas. Insulin secretion begins at approximately the fifth month. The acini develop from terminal ductal cells. The ductal system and the acini collectively become the exocrine portion of the pancreas.⁶ Secretory activity probably becomes established in the pancreas during the second trimester, although this has been disputed.¹ The weight of the pancreas, which is 5 to 5.5 g at birth, will increase to 15 g at the end of the first year.¹¹

The process of pancreatic fusion is complicated, and a wide spectrum of anomalies or anatomic variants related to this process may appear—for example, agenesis, aplasia of the pancreatic anlage, hypoplasia, annular pancreas, and pancreas divisum.¹²

Variants of Normal Anatomy

The lateral aspect of the head and neck of the pancreas can have varieties of shapes and occasionally look prominent (Fig. 96-4). However, many of the contour variations may represent a spectrum of fusion patterns that cannot be attributed to pancreas divisum alone.^{13,14} A deep cleft separating two distinct pancreatic moieties may be identified on computed tomography (CT) scans in the head and neck of the pancreas in patients with pancreas divisum.

The pancreas is surrounded by fat that clearly defines its margin. However, because of the lack of any pancreatic capsule, the pancreatic lobules can be outlined by fat. Such fatty infiltration can be diffuse or focal (Fig. 96-5). Focal fatty infiltration can mimic a mass on CT, particularly if there is associated lobulation (see Fig. 96-4). Therefore, magnetic resonance imaging (MRI) may become necessary to differentiate this benign

Figure 96-1 Pancreatic duct development. **A.** The dorsal pancreatic segment grows posteriorly into the dorsal mesentery, and the ventral anlage develops as an outpouching from the base of the hepatic diverticulum and grows in the ventral mesentery. **B.** The ventral component transiently develops into a bifid structure. The ventral pancreas and the bile duct system will be carried posteriorly as the duodenum matures. **C.** The final stage of pancreatic duct maturation entails fusion of the two systems. (A–C from Taylor AJ, Bohorfoush AG: *Interpretation of ERCP: With Associated Digital Imaging Correlation*. Philadelphia, Lippincott-Raven, 1996, pp 209–210.)

Figure 96-2 Duct of Wirsung. Notice the junction of the ventral duct and common bile duct at the ampulla with total regression of the dorsal duct.

Figure 96-3 Variation of accessory duct appearance. After the dorsal-ventral system fusion, the original dorsal duct segment draining into the duodenum may remain as the duct of Santorini (**A**), serving as a slender, narrowed connection of the main pancreatic duct (MPD) with the duodenum through the minor papilla; maintain connection with the MPD but not drain into the duodenum (**B**), thereby becoming another MPD side branch; maintain communication with the duodenum at the minor papilla but lose connection with the MPD (**C**); or maintain connection with both the duodenum and the MPD but develop a circuitous course forming the ansa pancreatica (**D**). (A–D from Taylor AJ, Bohorfoush AG: *Interpretation of ERCP: With Associated Digital Imaging Correlation*. Philadelphia, Lippincott-Raven, 1996, pp 209–210.)

Figure 96-4 Pancreatic head lobulation and fatty infiltration.

A. Contrast-enhanced CT scan shows lateral lobulation of the pancreatic head (arrow) with heterogeneous density due to fatty infiltration. **B.** Upper portion of the head, body, and tail are spared fatty infiltration.

process from a neoplasm (Fig. 96-6). Fatty infiltration may be associated with focal sparing of pancreatic parenchyma, and that should not be mistaken for tumor.

The position and configuration of the pancreas are variable, and these variations may simulate pathologic conditions. For example, the pancreatic head is not fixed in position, although it almost invariably maintains a fixed relationship medial to the second portion of the duodenum and lateral to the root

of the superior mesenteric vessels, even if these structures are shifted to the left of the midline. Although the splenic vein usually marks the dorsal margin of the body and tail of the pancreas, the tip of the gland may rarely curve dorsal to the splenic vein to simulate adrenal abnormalities (Fig. 96-7). On occasion, even in normal persons, the pancreatic tail may be anterior-lateral to the left kidney, where it may appear as a pseudomass on excretory urography. In patients with prior

Figure 96-5 Fatty infiltration of the pancreas. **A.** CT of the pancreatic head reveals a large area of fatty infiltration in the head of the pancreas (arrows). A portion of the uncinate process is spared from fat. Notice lack of any mass effect on the adjacent superior mesenteric vein. **B.** Fatty infiltration is also present in the pancreatic body. The tail is spared.

Figure 96-6 Focal fatty infiltration in the pancreatic head in a 42-year-old woman. **A.** Contrast-enhanced CT study reveals an area of hypodensity in the head of the pancreas (arrows) that appears to spare a portion of the uncinate process (U). Posterior to the head, one can see the unopacified duodenum. **B.** Out-of-phase sequence MR image without contrast (TR 163, TE 2.38) reveals low signal intensity fat corresponding to the hypodense area on the CT scan. Again, note duodenum (D) in the posterior lateral aspect of the head and fatty spared area in the region of the uncinate process (U). **C.** Axial CT image of the head and body at the higher level reveals that the remainder of the pancreas appears to be spared from significant fatty infiltration.

Figure 96-7 Extension of the pancreatic tail into the adrenal fossa. Notice as a normal variant, the splenic vein (arrows) no longer serves as the ventral pancreatic landmark. The top and bottom images are continuous 5-mm slices.

left nephrectomy or in those with congenital absence of the left kidney, the pancreatic tail is often displaced into the renal fossa, which may simulate recurrent tumor or a primary retroperitoneal lesion.¹⁵

Kreel and colleagues¹⁶ published a set of in vivo and in vitro measurements of pancreatic dimensions and concluded that the normal diameter of the head is up to 3 cm, that of the neck and body up to 2.5 cm, and that of the tail up to 2 cm. However, the size, shape, and position of the normal pancreas are highly variable (Fig. 96-8), and there is usually a gradual tapering from the head to the tail without abrupt alterations in size or contour. There is gradual decrease in the size of the pancreas with advancing age, sometimes becoming very small beyond the seventh decade. Fatty lobulations are more commonly observed in obese and elderly individuals. Rarely, an accessory spleen can be embedded in the tail of the pancreas, and MRI or a nuclear medicine study may be needed to differentiate this variant from a mass (Fig. 96-9).

Bifid pancreatic duct (Fig. 96-10) is a rare anatomic anomaly in which the main pancreatic duct is bifurcated along its length. It is associated with a high incidence of pancreatitis.¹⁷

Figure 96-8 Normal variant pancreas in which the tail (arrows) is more prominent than the head and proximal body. Notice homogeneous enhancement of pancreas and normal lobulations of its borders.

Congenital Anomalies of the Pancreas

PANCREAS DIVISUM

In this anomaly, the pancreas is divided in two separate parts as a result of an absent or incomplete fusion of the ventral and dorsal anlagen. As a consequence, the pancreatic head and uncinate process are drained by the duct of Wirsung through the major papilla; the body and tail are drained by the duct of Santorini through the minor papilla^{18,19} (Fig. 96-11). This anomaly is seen in 4% to 11% of autopsy series and 3% to 4% of endoscopic retrograde cholangiopancreatography (ERCP) series.²⁰⁻²³ In an analysis of 650 ERCP studies done by Uomo and coworkers,²⁴ 485 patients had satisfactory imaging of the pancreatic ducts, whereas in 48 cases (9.9%), anatomic variants of the duct were found. These included fusion variants in 26 cases (22 pancreas divisum and 4 functional divisum) and duplication variants in 22 patients (1 bifurcation of the main pancreatic duct, 4 loop, 2 N shaped, and 3 ring).

Clinical Findings

Although the anatomic variant of pancreas divisum has been well known for some time, its clinical significance has become evident with the advent of ERCP. Most cases of pancreas divisum are asymptomatic. This anomaly may contribute to recurrent episodes of idiopathic pancreatitis in younger patients with no risk factors.^{25,26} Between 12% and 26% of patients with idiopathic recurrent pancreatitis have this anomaly, as opposed to 3% to 6% in the general population.^{22,26} The age at presentation varies widely but is most commonly between 30 and 50 years.²⁷ Several reports of pancreatitis associated with pancreas divisum in children have appeared, and there is a report of this anomaly occurring in multiple family members.²⁸

It is postulated that in pancreas divisum, the duct of Santorini and its accessory ampulla are too small to adequately drain the volume of secretions produced by the pancreatic body

Figure 96-9 Accessory spleen within the tail of the pancreas mimicking a mass. **A.** The contrast-enhanced fat suppression T1-weighted MR image that was obtained because of the patient's left upper quadrant pain reveals areas of infarction of the spleen. There is a well-defined homogeneous mass in the tail of the pancreas displaying signal intensity similar to that of the upper part of the spleen (not shown). **B.** On review of the contrast-enhanced CT scan that was obtained 2 years earlier, the mass has not changed. On a prior study, it was presumed to represent spleen, and a nuclear medicine examination proved the nature of the mass to be accessory spleen in the tail of the pancreas.

Figure 96-10 Bifid pancreatic duct. **A.** A half-Fourier half-acquisition single-shot turbo spin-echo (HASTE) sequence was used for magnetic resonance cholangiography, which showed a dilated common bile duct due to a distal stone. However, a bifid pancreatic duct (arrows) was incidentally demonstrated. **B.** ERCP clearly demonstrated bifurcation of the pancreatic duct (bifid) throughout the body of the pancreas (arrowheads). (Courtesy Dr. Ann S. Fulcher, Medical College of Virginia, Richmond, VA.)

and tail.²⁹ In a manometer study, patients with pancreas divisum had significantly higher pressure readings of the dorsal duct cannulated through Santorini than of the ventral duct cannulated through Wirsung. The study concluded that in pancreas divisum, there is chronic stasis of pancreatic fluid that, compounded by additional factors such as alcoholism, causes greater viscosity, which increases the risk of pancreatitis.²⁶ Surgical sphincteroplasty of the accessory sphincter has been advocated as an important means of preventing recurrent bouts of pancreatitis in these patients.³⁰⁻³³

Association of pancreatic divisum with pancreatic tumors has been reported.³⁴⁻³⁸ In a limited study, pancreatic tumors were detected in 12.5% of patients with divisum.³⁴ The authors believed that relative stenosis of the minor pancreatic duct and long-standing pancreatic obstruction might be risk factors for development of pancreatic cancer.

There are some other problems associated with divisum, like santorinicele or cystic dilation of the dorsal pancreas at the

minor papillae, that may indicate obstruction at the minor papilla.³⁹ Also, cases of multiple neuroendocrine tumors of the pancreas⁴⁰ and intestinal malrotation⁴¹ have been reported in association with pancreas divisum.

Radiologic Findings

Endoscopic Retrograde Cholangiopancreatography. ERCP is often considered the effective modality for confirming a diagnosis of pancreas divisum.²²⁻²⁴ Often, injection of contrast material into the duct of Wirsung is met with resistance and even pain. However, after opacification, the duct is short and tapered, and acinarization commonly occurs as the endoscopist attempts to fill the "remainder" of the duct. This duct tapers gradually from the orifice, sending branches in the pancreatic head.^{21,42} It must be differentiated from a duct that appears foreshortened secondary to previous trauma, partial pancreatectomy, pseudocyst, or stricture caused by carcinoma or pancreatitis. In these cases, the pancreatic duct typically has an abrupt or irregular

Figure 96-11 Pancreas divisum. **A.** Diagram. Note that the pancreatic head and uncinate process (ventral duct) along with the common bile duct drain into the major papilla, whereas the body and tail (dorsal duct; arrow) drain into the minor papilla. **B.** Axial contrast-enhanced CT study through the head of the pancreas reveals two separate pancreatic ducts draining into the duodenum. Other images prove the separate nature of these ducts, the upper one (arrow) draining the head and body of the pancreas into the minor papilla and the lower one (arrowhead), only from the inferior head and the uncinate process, draining into the major papilla. **C.** Coronal oblique thick-slab MRCP image reveals that the pancreatic duct drains through the minor papilla (single arrow). The duct of Wirsung is also depicted (double arrows) without connection between the two systems. The findings are consistent with complete pancreas divisum. This image was obtained after secretin injection. (Courtesy Dr. Carmen DeJuan, Department of Radiology Hospital Clinic, University of Barcelona, Spain.)

terminus.²¹⁻²³ The duct of Santorini is often not visualized by injection of the major papilla, and if cannulation is successful, the full-length duct of Santorini is seen without communication to the smaller duct. Otherwise, the diagnosis can be made by secretin stimulation and identification of secretions emanating from the minor papilla only. See Chapter 74 for more details.

Linear Array Endoscopic Ultrasonography. Endoscopic ultrasonography (EUS) frequently allows detailed imaging of the pancreatic parenchyma and ductal system. It has been reported that with the use of radial instruments, if the portal vein, common bile duct, and main pancreatic duct could be demonstrated in one image, the diagnosis of pancreatic divisum would be excluded. This is considered an indirect assessment for the evaluation of pancreatic divisum.⁴³ Therefore, with a linear array instrument, if the main pancreatic duct passes from the major papilla to the pancreatic body and tail, or if the duct crosses the border separating the ventral and dorsal anlagen, the diagnosis of pancreatic divisum is excluded. Lai and associates⁴⁴ reported the sensitivity, specificity, and accuracy of this method for diagnosis of pancreas divisum to be 95%, 97%, and 97%, respectively. There are some merits for EUS over magnetic resonance cholangiopancreatography (MRCP), and perhaps ERCP, as it allows direct visualization and fine-needle aspiration biopsy of pancreatic masses that otherwise may lead to the

ductographic phenomenon of pseudodivisum. This could conceivably result from the presence of apparently separate ventral and dorsal ductal systems due to mechanical obstruction near the expected point of connection between these two systems.⁴⁴ Also, EUS seems to be less invasive than ERCP because EUS does not involve pancreatic duct cannulation or injection of contrast material, which is a risk factor for development of iatrogenic pancreatitis.⁴³⁻⁴⁷ Therefore, linear array EUS appears to be a promising, minimally invasive diagnostic imaging modality for the detection of pancreas divisum.^{43,44}

Sonographic Secretin Test. In an attempt to identify patients who will benefit from surgical sphincterotomy, several tests have been proposed to assess the adequacy of the accessory papilla in transmitting pancreatic secretions. In the sonographic secretin test, the main pancreatic duct is sonographically monitored before and after the intravenous administration of secretin (1 unit/kg body weight).⁴⁸ Secretin-induced dilation occurs in 72% of symptomatic patients found to have a stenotic accessory papilla associated with pancreas divisum. The sonographic secretin test is also highly controversial; several authors have demonstrated that dilation of the pancreatic duct can be a normal finding.⁴⁹⁻⁵¹ In addition to surgery, pancreas divisum can be treated by percutaneous dilation and stent placement.^{52,53}

Computed Tomography. Contour abnormalities of the pancreatic head and neck have been identified on CT in some patients with pancreatic divisum.⁵⁴ CT can occasionally suggest this diagnosis when two distinct pancreatic moieties or an unfused ductal system is identified on thin-collimation scans (see Fig. 96-11). The two moieties may cause pancreatic head enlargement or may be separated by a fat cleft. Sometimes, fatty replacement of the dorsal pancreas may delineate it from the ventral moiety.^{30,54} Also, the pancreatic head may be spared from atrophy and pancreatitis affecting the body and tail, which produces a pseudotumor on CT and ultrasound studies.⁵⁵ In alcoholics, isolated ventral pancreatitis may occasionally be observed, which suggests a synergism between the effects of alcohol and bile reflux into the ventral pancreas. The dorsal pancreas is spared this reflux because of the pancreas divisum.⁵⁶ Other ductal anomalies may also produce masses on cross-sectional imaging.^{57,58}

Multidetector CT with high-resolution oblique coronal image reconstruction assists in the depiction of the continuity of pancreatic ducts. The sensitivity and specificity of this method for diagnosis of pancreatic divisum are reported to be 100% and 89%, respectively.⁵⁹

Magnetic Resonance Cholangiopancreatography. Heavily T2-weighted, two-dimensional, fast spin-echo sequences using a body coil can often accurately depict pancreatic ductal anomaly and establish the diagnosis of pancreas divisum.⁶⁰ Gradient sequences using breath hold have been found useful for evaluation of the pancreatic and biliary system. MRCP is superior to ERCP for visualizing the pancreatic ducts, especially with the use of half-Fourier acquisition single-shot turbo spin-echo (HASTE) sequence.⁶¹ However, MRCP with single-shot rapid acquisition with relaxation enhancement may be superior to HASTE for increasing pancreatic duct conspicuity.⁶²

When T1-weighted sequences with fat suppression are performed,^{63,64} MRCP allows visualization of not only the pancreatic ducts but also the pancreatic parenchyma around the duodenum. Indeed, MRCP may be able to replace ERCP in the diagnosis of pancreas divisum.

Secretin-stimulated MRCP has been used in the diagnosis of santorinicele or cystic dilation of dorsal pancreas at the minor papillae and also for pancreas divisum^{39,65,66} (see Fig. 96-11). See Chapter 75 for more detail concerning MRCP.

ANNULAR AND SEMIANNULAR PANCREAS

Annular pancreas is a rare congenital anomaly occurring in 1 of every 12,000 to 15,000 live births. In this anomaly, the

annulus is often a flat band of pancreatic tissue completely encircling the second portion of the duodenum^{21,23} (Figs. 96-12 and 96-13). Unusual locations of annular pancreas have also been reported to be around the third portion of the duodenum.⁶⁷

In normal pancreatic development, the ventral anlage develops as two separate buds from the hepatic diverticulum. The left ventral bud atrophies, and the right ventral bud persists to form the head and uncinate process. The ventral anlage undergoes 180-degree counterclockwise rotation while the duodenum undergoes 90-degree clockwise rotation, so that the ventral anlage occupies a position contiguous with the dorsal anlage, medial to the duodenum. There are three theories concerning the formation of the annular pancreas: hypertrophy of both the dorsal and the ventral ducts, resulting in a complete ring; adherence of the ventral duct to the duodenum before rotation; and hypertrophy or adherence of the left bud of a paired ventral primordium.⁶⁸

Clinical Findings

Annular pancreas is an uncommon congenital anomaly that may be manifested clinically in the neonate (52%) or may be asymptomatic until adulthood (48%). This disorder is not usually manifested clinically until the third to fifth decade of life⁶⁹⁻⁷¹ or even occasionally later.⁷²

Symptoms are usually related to duodenal obstruction. Neonates present with vomiting on the first day of life, and there often is an antecedent history of polyhydramnios and other manifestation of fetal gastrointestinal tract obstruction.^{23,42,73,74} A number of other anomalies, such as intestinal malrotation, duodenal atresias of various forms, and cardiac anomalies, are often present as well.

Annular pancreas may be quiescent and not cause symptoms until adulthood. Kiernan and associates⁷⁵ reviewed 266 patients with symptoms and found that 48% were adults. In older children and adults, nausea, vomiting, and epigastric pain are the chief presenting complaints. The incidence of associated gastric and duodenal ulcers ranges from 26% to 48%, and pancreatitis develops in 15% to 30% of patients. The obstruction of the duodenum in these patients is apparently not sufficient to cause symptoms until there is supervening peptic ulcer disease or pancreatitis.⁷⁶⁻⁷⁸ There are reports of extrahepatic biliary obstruction due to annular pancreas.^{3,5}

In a 10-year review of annular pancreas in children, Jimenez and colleagues⁷⁹ found that among 16 patients, 12 (75%) presented within the first week of life, 5 (31%) had chromosomal anomalies, and 6 had other major congenital problems. In another review of seven cases with annular pancreas, four patients (42.8%) had associated anomalies, including intestinal

Figure 96-12 Annular pancreas. A and B. Drawings illustrate the probable embryologic basis of annular pancreas. C. An annular pancreas encircles the duodenum. (A and B from Moore KL: *The Developing Human*, 4th ed. Philadelphia, WB Saunders, 1988.)

Figure 96-13 Annular pancreas. **A.** Annular pancreas presenting in neonatal period with narrowing (arrows) of descending duodenum. Duodenal bulb (D) and stomach (S) are dilated, producing the classic double-bubble sign. **B.** Annular pancreas is manifested as concentric duodenal narrowing (arrows) in this adult patient who had nondescript epigastric pain. **C.** Diagram illustrates the pathologic process shown on the barium study. (C from Gray SW, Skandalakis JE, Skandalakis LJ: *Embryology and congenital anomalies of the pancreas*. In Howard JM, Jordan GL, Reber HA [eds]: *Surgical Disease of the Pancreas*. Philadelphia, Lea & Febiger, 1987, pp 37–45.)

malrotation (42.8%), intrinsic duodenal obstruction (28.5%), trisomy 21 karyotype (14.2%), cardiac malformation (14.2%), and Meckel's diverticulum (14.2%).⁸⁰ The authors concluded that annular pancreas is most commonly associated with intestinal malrotation.

In the pediatric population, symptomatic annular pancreas is best treated by a bypass procedure such as gastrojejunostomy or duodenojejunostomy.^{17,48} However, in adults, a variety of surgical as well as interventional endoscopic procedures are used therapeutically.

Pancreatic malignant disease in the setting of annular pancreas has been reported, most often arising from the ventral bud.^{81,82} However, involvement of the dorsal bud has also been reported.^{83,84} Evaluation of the pancreas for malignant disease is recommended in cases of annular pancreas presenting with obstructive jaundice.^{85,86}

Radiologic Findings

Plain Radiography and Barium Studies. Pediatric patients with annular pancreas often have diagnostic findings on plain radiographs with the double-bubble sign (see Fig. 96-13A); the proximal bubble is caused by gastric distention and the distal bubble by a dilated duodenal bulb.^{23,25,75}

The radiographic findings on upper gastrointestinal barium studies are often characteristic and are best demonstrated when the duodenum is maximally distended. Stenosis is demonstrated in the periampullary region associated with an extrinsic eccentric defect on the medial margin of the second portion of the duodenum (Fig. 96-13B). The mucosa is intact unless there is associated peptic ulcer.⁸⁷ Peptic ulcer disease is common, so when an ulcer is seen in the periampullary duodenum in an adult, the diagnosis of annular

pancreas as well as Zollinger-Ellison syndrome should be considered.^{23,25}

Endoscopic Retrograde Cholangiopancreatography. Diagnosis of annular pancreas is most commonly suggested by ERCP, which shows typical features in about 85% of cases. In these patients, a normally located main pancreatic duct is seen in the body and tail that communicates with the small duct of the pancreatic head, which encircles the duodenum. This latter duct is seen originating on the right anterior surface of the duodenum, passing posteriorly around the duodenum and entering the main pancreatic or common bile duct near the ampulla. In some patients, biliary obstruction may be seen as well.

Computed Tomography. Findings on CT are often nonspecific, showing enlargement of the pancreatic head that has a central region of high attenuation representing contrast material within the narrowed duodenal segment. If the duodenum is not sufficiently opacified, only pancreatic head enlargement may be noted.⁸⁸ Other CT findings include apparent circumferential thickening of the duodenal wall in association with an enlarged pancreatic head. A peninsular protrusion of pancreatic tissue may also be seen in the duodenal lumen.^{89,90} Review of continuous images on a monitor provides the opportunity to follow the duodenum from above as it enters the encircling pancreatic head and then exits inferiorly. On occasion, the duodenum may not be completely encircled with pancreatic tissue. This anomaly is called semiannular pancreas. Ueki and colleagues⁹¹ reported that three-dimensional CT pancreatography may be useful in clarifying embryogenesis of annular pancreas.

Ultrasound. Nonspecific enlargement of the pancreatic head is the major sonographic abnormality seen in annular pancreas.⁹⁰ EUS is more accurate in making the diagnosis.⁹²

Magnetic Resonance Imaging. Fat-suppressed T1-weighted sequence may show a normal-appearing pancreatic tissue encircling the duodenum.⁹³ MRI as well as CT (Fig. 96-14) may be used as a problem-solving technique to supplement the conventional studies.^{94,95} Because CT may show only an enlarged pancreatic head, MRI is able to clearly discriminate the pancreas from the duodenum.⁹⁶

Angiography. Celiac angiography may demonstrate an anomalous branch from the posterior pancreaticoduodenal artery that courses in a right and inferior direction to supply the annular moiety.^{23,42}

ECTOPIC PANCREATIC TISSUE

Heterotopic pancreas in which glandular acini ducts and well-differentiated islets can be recognized microscopically is rare. It is seen in organs derived, like the normal pancreas, from entoderm. Heterotopic pancreas is the result of heteroplastic differentiation of parts of embryonic entoderm that do not normally produce pancreatic tissue.¹¹ Although the embryonic origins of the pancreas and liver are close anatomically, ectopic pancreas is much more common than heterotopic liver.^{1,10,97,98}

These ectopic rests of pancreatic tissue most commonly occur in the gastric antrum (25.5%) or proximal portion of the duodenum (27.7%). Less frequent sites include jejunum (15.9%), ileum, Meckel's diverticulum, colon, appendix, mesentery, omentum, liver, gallbladder, spleen, bile ducts, esophagus, mediastinal cyst,⁹⁹ fallopian tube, and bronchoesophageal fistula.^{19,22,42,100-103} When it is present in the walls of the duodenum and stomach, heterotopic pancreas is usually composed of normal pancreatic tissue, including islet cells, and a small pancreatic duct. Islet cells are usually absent at other sites. The ectopic pancreatic tissue usually lies submucosally (73%), although it can be located in the muscularis mucosae or on the serosal surface of the gut.^{104,105} Formation of cyst in association with duodenal heterotopic pancreas in pancreas divisum has also been reported.^{104,105}

Ectopic pancreatic tissue is functional and subject to the same inflammatory and neoplastic disorders that afflict the normal pancreas. The majority of cases, however, are asymptomatic and found incidentally.¹⁰³⁻¹⁰⁹ Indeed, many reported cases of pancreatic heterotopia in the duodenum are found incidentally during peptic ulcer surgery. Also, pancreatic tissue was found in the duodenum by careful sectioning in nearly 14% of autopsies, and pancreas-like tissue is also found in 14.1% of postmortem studies of the biliary system. When it is symptomatic, ectopic pancreas may simulate duodenal ulcer, gallbladder disease, or even appendicitis.^{105,108} In the stomach, it may be a component of tumor-like lesions that cause symptoms such as pyloric obstruction.¹⁰⁷ Perivaterian pancreatic tissue may cause

Figure 96-14 Annular pancreas: MR features. **A.** Axial fat saturation T1-weighted image shows the duodenum surrounded by pancreatic tissue (arrows). **B.** Coronal oblique thick-slab MRCP image demonstrates the duct of the annular pancreas (arrows) that forms a complete loop around the duodenum. This examination was performed after secretin administration. (Courtesy Dr. Carmen DeJuan, Department of Radiology Hospital Clinic, University of Barcelona, Spain.)

Figure 96-15 Ectopic pancreas: barium contrast studies. Ectopic rests of pancreatic tissue are present in the gastric antrum (**A**) and duodenal bulb (**B**). The mound of pancreatic tissue is signified by the open arrows. The solid arrow shows the draining duct.

biliary obstruction, and if the ectopic tissue is located more distally, it may serve as a lead point for intussusception.¹¹⁰ Symptomatic lesions tend to be larger than 1.5 cm, and malignant tumor has been reported to arise from these tissue rests.^{107,109}

No specific treatment is necessary in this disorder unless the ectopic pancreatic tissue is causing symptoms, such as obstruction or hemorrhage.

Radiologic Findings

Ectopic pancreas characteristically appears as a broad-based, smooth, extramucosal or intramural lesion either along the greater curvature of the gastric antrum or in the proximal duodenum (Fig. 96-15). A small collection of barium appearing as a central niche or umbilication is diagnostic and present in 45% of cases. This represents the orifice of the rudimentary duct into which the ectopic pancreas empties.⁹⁵ This pit may be as large as 5 mm in diameter and 10 mm in length. If this feature is absent, the lesion cannot be differentiated from other submucosal tumors.^{22,23,42} The differential diagnosis includes peptic ulcer disease, gastric polyp, Brunner gland adenoma, gastrointestinal stromal tumor, lymphoma, and metastasis to the stomach such as malignant melanoma or Kaposi's sarcoma.¹¹¹ Rarely, large intramural cystic collections can be seen in the stomach and duodenum on CT scans.¹¹²

AGENESIS, HYPOPLASIA, AND HYPERPLASIA OF THE PANCREAS

Agenesis of the pancreas is rare and typically incompatible with life. A causal relationship with intrauterine growth retardation has been noted and is presumed to be due to the lack of fetal insulin necessary for development.¹¹³ Partial pancreatic agenesis and hypoplasia are also rare; however, cases of agenesis of the

dorsal pancreas have been reported¹¹⁴ along with malrotation. Abnormal rotation of the intestine may interrupt the normal rotation of the pancreatic primordium, with malpositioning of the pancreatic buds resulting in abnormal morphology of the uncinate process.¹¹⁵

DUCTAL ABNORMALITIES

The single main pancreatic duct normally connects with the accessory duct of Santorini, and then they open in conjunction with the common bile duct at the ampulla of Vater. This arrangement is seen in 60% to 70% of normal individuals.^{116,117} The common variations of pancreatic ductal anatomy include junction of the ventral duct and common bile duct at the ampulla with complete regression of the dorsal duct (see Fig. 96-2) (40%-50%); junction of the ventral and common bile ducts at the ampulla but with persistence of the dorsal duct (35%); persistence of both the dorsal and the ventral ducts without communication, or pancreas divisum (5%-10%); common channel with a retroduct entering the common duct 5 to 15 mm from the ampulla (5%-10%); and separate entrance of the ventral duct into the duodenum with variable persistence of the dorsal duct (5%).¹¹⁶⁻¹¹⁹ Variations in ductal configurations include a sigmoid configuration of the duct and descending course of the duct. One may rarely encounter a loop at the point of the embryologic fusion of the ducts.

CONGENITAL CYSTS

The cystic lesions that are congenital and not related to cystic fibrosis of the pancreas are rare. Such cysts do not cause any symptoms, have a thin fibrosed wall, and are lined by a columnar or cubicle type of epithelium. They are not associated with cysts in any other organs.¹¹⁸⁻¹²²

Radiologic Findings

Summary

Pancreatitis is one of the most complex and clinically challenging of all abdominal disorders. It remains a major diagnostic challenge because its clinical manifestations are as protean as its causes. Indeed, only one in five severe cases of acute pancreatitis is recognized to be severe at initial presentation,¹⁻³ and 42% of fatal cases of acute pancreatitis do not have a correct diagnosis before autopsy.⁴⁻⁷

Since the late 1970s, cross-sectional imaging and, in particular, high-resolution, bolus contrast-enhanced multidetector helical computed tomography (CT) have dramatically improved the diagnosis and treatment of acute pancreatitis. More recently, magnetic resonance imaging (MRI) has shown that it can have a role in imaging of patients with pancreatitis. The focus of this chapter is on the contribution of radiology to the assessment and management of patients with acute or chronic pancreatitis.

Classification of Pancreatitis

Pancreatitis is classified according to clinical, morphologic, and histologic criteria on the basis of the Marseille and Cambridge symposia and the 1992 International Symposium in Atlanta, Georgia,^{8,9} and more recently the Acute Pancreatitis Classification Working Group in 2008.¹⁰⁻¹²

Acute Pancreatitis

ETIOLOGY

Although the causes of pancreatitis are diverse, alcoholism and biliary tract disease (gallstones) account for approximately 90% of cases in the United States. The relative frequency of these causes varies with the country and population of patients examined. Alcoholic pancreatitis is more common in urban

and Veterans Administration hospitals, whereas gallstone pancreatitis predominates in suburban and rural hospitals. The incidence of acute pancreatitis is 0.005% to 0.01% in the general population.¹³⁻¹⁸ Approximately 10% to 30% of patients with acute pancreatitis will never have the cause of the disorder established and are given the diagnosis of “idiopathic” pancreatitis. Biliary sludge and microlithiasis are probably responsible for the development of pancreatitis in the majority of these cases.^{16,19,20}

Identification of the cause of pancreatitis is important because it helps determine therapy. It may limit further unnecessary examinations and may improve the patient’s long-term outcome.¹⁶

PATHOPHYSIOLOGY

The precise mechanisms of pathogenesis of acute pancreatitis are not completely understood. Alcohol increases the risk for pancreatitis through multiple mechanisms. More than 95% of heavy alcohol users, however, never develop significant pancreatitis, which suggests that this is a complex syndrome, with other risk factors involved.^{21,22} Hypotheses and theories to explain alcoholic pancreatitis include necrosis-fibrosis sequence, duct obstruction, leakage of enzymes from the pancreatic duct, abnormal synthesis of digestive enzymes, toxic metabolites, altered pancreatic blood flow, mitochondrial damage, and activation of pancreatic stellate cells, which produce collagen in the fibrotic pancreas.²²

In alcoholic pancreatitis, the toxic effect and chemical alterations of the exocrine secretions produced by alcohol lead to protein precipitates that obstruct the pancreatic ducts.^{23,24} In addition, alcohol can lead to duodenitis, edema, and spasm of the papilla of Vater, further contributing to ductal obstruction.²³

Alcohol also indirectly stimulates pancreatic secretion by inducing an increase in gastrin and secretin levels and decreases the level of zymogen inhibitor, resulting in the premature activation of trypsin.²⁴ In acute pancreatitis, these activated pancreatic enzymes are extravasated, causing pancreatic autodigestion and necrosis.²⁵ In cholelithiasis-induced pancreatitis, there is obstruction of the common biliopancreatic channel by a stone (Opie stone), with resultant reflux of bile into the pancreatic duct and activation of pancreatic enzymes.^{17,25} Gallstones are found in the stool of most of these patients.²⁶ This is the rationale for emergency cholecystectomy or endoscopic retrograde cholangiopancreatography (ERCP)-directed sphincterotomies in the treatment of gallstone pancreatitis.¹⁶ Reflux of contrast material into the pancreatic duct during intraoperative cholangiography is much more common in patients with gallstone pancreatitis than in patients undergoing cholecystectomy who do not have pancreatitis.^{15,27}

Pancreas divisum, discussed in detail in Chapter 96, is also postulated to induce this disorder by a functional obstruction

at the accessory papilla of Santorini.²⁸ A variety of other causes, such as drugs, calcium, endotoxins, hyperlipidemia, viral infections, ischemia, anoxia, and trauma, can also activate proteolytic enzymes in the pancreas that lead to autodigestion and stimulate other enzymes, such as bradykinin and vasoactive substances, that cause vasodilation, increased vascular permeability, and edema.^{15,29}

Leukocytes attracted by the pancreatic injury release inflammatory mediators called cytokines, which have an important role in disease progression and multisystem complications of acute pancreatitis. Biologically active compounds, such as phospholipase A₂, tumor necrosis factor, polymorphonuclear cell elastase, complement factor, interleukins, and leukotrienes, are released into the systemic circulation, stimulating the production of other mediators and leading to distant organ failure.³⁰⁻³² Some of these mediators, such as tumor necrosis factor, are also toxic to acinar cells and may contribute to pancreatic injury and necrosis.^{32,33} These inflammatory products occur early in the course of the disease and can be used as indicators of severity and prognosis in acute pancreatitis.^{32,34,35}

Pancreatitis has been shown to have an increased prevalence in patients with acquired immunodeficiency syndrome (AIDS), explained either by the effects of medication (pentamidine and 2',3'-dideoxyinosine [DDI]) or by secondary opportunistic infections.^{1,16,36}

No dependable correlation exists between the etiology and the severity of disease. In general, most cases of necrotizing pancreatitis are associated with alcoholism and hyperlipidemia, whereas severe pancreatitis is less commonly noted with other causes.

There are several major pathologic categories of acute pancreatitis. Acute interstitial edematous pancreatitis is the mildest form of pancreatitis. It is characterized by absent or minimal pancreatic and systemic dysfunction and a rapid response to medical therapy without complications. Only pancreatic edema and mild cellular infiltrate are present. The gland may enlarge to three times its normal size and become firm. There may be a few small, scattered foci of necrosis and saponification in the peripancreatic fatty tissue. Other organs generally are not involved. Necrotizing pancreatitis is a far more severe form of pancreatitis in which varying degrees of systemic and distal organ failure and potentially lethal complications can occur. Extensive fat necrosis, hemorrhage, and necrotic liquefaction of the pancreatic parenchyma and adjacent peripancreatic tissues and fascial planes are seen. In addition, a variety of intermediary forms of pancreatitis occur in clinical practice. The degree and extent of injury appear to be related to the quantity, rate of production, and activity of the highly lipolytic and proteolytic extravasated enzymes.¹⁶

DEFINITIONS

Considerable ambiguity and overlap of pathologic features exist in describing the complications of pancreatitis. The following are definitions of commonly encountered sequelae that are discussed in subsequent sections.^{16,37}

Acute pancreatitis is diagnosed when two of the three following criteria are present: (1) abdominal pain related to acute pancreatitis, (2) serum amylase or lipase activity greater than three times the normal level, and (3) imaging findings characteristic of acute pancreatitis.

According to the revised Atlanta classification of acute pancreatitis, acute pancreatitis can be divided into two major types: interstitial edematous pancreatitis and necrotizing pancreatitis.^{10,11}

Interstitial Edematous Pancreatitis. Most patients have diffuse (or less commonly focal) pancreatic enlargement from interstitial edema. The pancreas enhances relatively homogeneously without necrosis, and there is peripancreatic inflammation with mild stranding or fluid. The clinical findings generally resolve within the first week.³⁸ When imaging is performed within the first days after onset of pancreatitis, it may be difficult to distinguish interstitial edematous pancreatitis from patchy necrosis. Follow-up contrast-enhanced CT 3 to 7 days later may be helpful in the distinction.³⁹

Acute Peripancreatic Fluid Collection. Fluid collection in peripancreatic regions typically occurs within 4 weeks of symptom onset, mostly after interstitial edematous pancreatitis. It lacks nonliquefied material and a definable wall.

Necrotizing Pancreatitis. On imaging, necrotizing pancreatitis is defined by lack of enhancement of the pancreatic tissue. Necrosis most commonly involves the pancreas and peripancreatic tissues, followed by the pancreas and, least commonly, the peripancreatic tissues. Necrotizing pancreatitis is quantified on the basis of studies by Balthazar as less than 30%, 30% to 50%, and more than 50%. More recently, it has been graded by modified CT as less than 30% or more than 30%.⁴⁰

Acute Necrotic Collection. Acute necrotic collection refers to a persistent collection containing fluid and necrotic material of various amounts associated with necrotizing pancreatitis. This collection accumulates in the pancreas or peripancreatic tissue and occurs within 4 weeks after development of necrotizing pancreatitis.

Pancreatic Pseudocyst. Pancreatic pseudocysts are localized collections of pancreatic fluid confined by a capsule of fibrous or granulation tissue; they typically develop during 4 weeks after an acute episode or can be associated with stigmata of chronic pancreatitis. Pseudocysts lack a true epithelial lining, which distinguishes this entity from a cyst or cystic neoplasm. They are manifestations of a local complication of acute non-necrotic pancreatitis and should not contain solid material. Current literature estimates that 50% of asymptomatic pseudocysts smaller than 6 cm resolve spontaneously.⁴¹ Pseudocysts larger than 7 cm in diameter are likely to require intervention, particularly in patients with alcoholic pancreatitis.^{37,42} Persistent pseudocysts often communicate with the pancreatic duct and have the potential to rupture, to bleed, to become infected, or to cause a pseudoaneurysm.^{30,43} Infected pseudocysts require drainage.

Walled-off Necrosis. Walled-off necrosis is a persistent collection of necrotic tissue with a thickened wall that lacks a true epithelial lining; it arises in the setting of necrotizing pancreatitis.¹⁰ This collection accumulates in the pancreas or peripancreatic tissue usually 4 weeks or more after onset of necrotizing pancreatitis and may or may not be infected. Unlike a pseudocyst, walled-off necrosis contains necrotic pancreatic parenchyma or fat.¹¹ The liquefied components may be better

characterized by MR or ultrasound, including endoscopic ultrasound (EUS), to guide drainage if it is required.

Phlegmon. Phlegmon is a term formerly used to imply the presence of a heterogeneous masslike enlargement of the pancreas and retroperitoneal tissues. It does not correlate with the presence of infection or necrosis. Because the term has different meanings to gastroenterologists, internists, and surgeons, it should be avoided according to the revised Atlanta criteria.¹⁰⁻¹²

Abscess. Pancreatic abscess develops from infected, extravasated pancreatic secretions. It usually occurs 3 weeks or more after the initial attack or may develop as a secondary infection of a pseudocyst. This term has fallen out of favor with the revised Atlanta classification system, and the term *infected pseudocyst* is used instead.^{10-12,39}

Pseudoaneurysm. A pseudoaneurysm is a focal area of dilation of a splanchnic artery that may occur as a result of inflammatory weakening of the arterial wall by enzymes liberated in acute pancreatitis. Pseudoaneurysms usually are found in the splenic, gastroduodenal, and pancreaticoduodenal arteries and can be freestanding or associated with a pseudocyst. Intermittent or life-threatening hemorrhage into a pseudocyst, retroperitoneum, or peritoneal cavity may occur.

CLINICAL FINDINGS

The clinical diagnosis of pancreatitis is often difficult. Patients' symptoms range from mild abdominal pain, nausea, vomiting, fever, tachycardia, and abdominal distention to severe abdominal pain and shock. Most patients have abdominal tenderness and guarding. These findings are nonspecific, and the differential diagnosis usually includes acute cholecystitis, bowel obstruction or infarction, perforated viscus, renal colic, duodenal diverticulitis, aortic dissection, appendicitis, and ruptured abdominal aortic aneurysm. In very severe cases, flank ecchymosis (Grey Turner's sign) or periumbilical hematoma (Cullen's sign) may be present.

Consequently, a battery of laboratory tests has been developed to diagnose and to grade pancreatitis. These tests include evaluation of serum amylase, lipase, serum/urinary amylase ratio, pancreatic isoamylase, immunoreactive trypsin, chymotrypsin, elastase, serum cyclic adenosine monophosphate, C-reactive protein, urinary trypsinogen-2, and methemalbumin.^{7,34,44} Serum amylase and lipase levels are the most commonly used measures to diagnose pancreatitis. Unfortunately, these values are elevated in only 80% to 90% of patients with acute pancreatitis.⁴⁵ Amylase is rapidly secreted by the kidneys and may return to normal levels during the first 48 to 72 hours.^{37,46} Pancreatitis caused by gallstones, microlithiasis, or drugs is often associated with a greater elevation in amylase than in lipase.^{47,48} The amylase level relative to lipase tends to be lower in alcoholic pancreatitis, hypertriglyceridemia-induced pancreatitis, neoplasia, and chronic pancreatitis.^{20,47,48} There is no correlation between the levels of serum amylase and the severity of acute pancreatitis; patients with mild forms of disease may exhibit levels above 1000 units, whereas patients with severe necrotizing pancreatitis may have normal or low amylase levels.^{49,50} Furthermore, hyperamylasemia may be seen in other acute abdominal conditions, such as bowel obstruction, bowel infarction, gangrenous cholecystitis, and perforated

ulcer.⁵¹ Elevated lipase is more specific for pancreatitis, but the level does not predict the etiology.⁵²

The onset of acute pancreatitis is defined from the time of onset of abdominal pain and not date of hospital admission. The clinical course of acute pancreatitis varies from mild and self-limited disease to shock, overwhelming sepsis, and death. The revised Atlanta classification divides acute pancreatitis into two broad categories: nonsevere acute interstitial edematous pancreatitis; and severe acute pancreatitis, which often involves necrosis of the gland or peripancreatic tissues.¹⁰ Characterization of acute pancreatitis can be considered on the basis of early and late phases of the disease.¹⁰ The early phase of acute pancreatitis appears within the first week and shows systemic reaction of the body to pancreatic enzymatic insults and injuries. This phase usually resolves within a week. The clinical features during this period are commonly the signs of systemic inflammatory response syndrome. The late phase of acute pancreatitis is seen only in moderately severe or severe acute pancreatitis. During this phase, local complications of acute pancreatitis and continuation of systemic signs of inflammation are noted; therefore, both clinical and imaging criteria are important.

Mild acute pancreatitis usually improves within the first week and during the early phase of disease. There is no evidence of organ failure or local or systemic complications of acute pancreatitis, and an imaging examination is often not needed in mild cases. Moderately severe acute pancreatitis is defined by the presence of local or systemic complications of acute pancreatitis or the existence of transient organ failure. By definition, transient organ failure in a patient suffering from acute pancreatitis lasts less than 48 hours. Severe acute pancreatitis determines when organ failure is evident for more than 48 hours.^{53,54}

RADIOLOGIC FINDINGS

Cross-sectional imaging has made a significant contribution to the diagnosis and staging of acute pancreatitis. Radiologic imaging of patients with suspected pancreatitis has five major objectives: (1) to exclude other abdominal disorders that can mimic acute pancreatitis; (2) to confirm the clinical diagnosis of acute pancreatitis; (3) to evaluate the extent and nature of pancreatic injury and peripancreatic inflammation in an attempt to stage the severity of disease; (4) to determine the etiology of acute pancreatitis; and (5) to serve as a guide for therapeutic intervention and response to therapy. Although plain films and contrast studies have been used in the past for the diagnosis of pancreatitis, they have been largely replaced by cross-sectional studies, which have significantly greater diagnostic accuracy. Findings and signs indicative of pancreatitis on different imaging modalities are briefly discussed here, with an emphasis on CT and MRI.

Abdominal Plain Films

Abnormalities in the abdominal gas pattern are the most frequent findings on abdominal plain films and range from a gasless abdomen to an ileus pattern. The most common findings are a small bowel ileus (42%), in which an adynamic sentinel loop is seen, and the colon cutoff sign (56%), related to spasm of the splenic flexure with distal paucity of gas caused by spread of the pancreatic inflammation into the phrenocolic ligament.⁵⁵⁻⁵⁹ Although it was originally described in abdominal

Figure 97-1 Colon cutoff sign on MDCT. **A.** Scout topogram for abdominal MDCT shows abrupt interruption (arrow) of colonic gas at splenic flexure in a patient with acute pancreatitis. **B.** Axial contrast-enhanced MDCT image shows narrowing (arrow) of the colonic lumen at the level of the splenic flexure as a result of extension of inflammatory exudate. **C.** Axial contrast-enhanced MDCT image shows pancreas (P) surrounded by inflammatory changes and fluid.

plain films, the colon cutoff sign can also be seen on CT (Fig. 97-1).

Chest Films

Approximately one third of patients with acute pancreatitis demonstrate pulmonary and chest abnormalities: elevated diaphragms, pleural effusions, basal atelectasis, pulmonary infiltrates, and the adult respiratory distress syndrome.⁶⁰⁻⁶⁵ Abnormalities on chest films can be useful to determine the severity of acute pancreatitis.^{66,67}

Barium Studies

Meyers and Evans⁶⁸ have emphasized the importance of the ligaments and mesenteries of the subperitoneal space (Fig. 97-2) in the spread of pancreatitis to understanding of the radiographic findings. Extravasated pancreatic enzymes commonly enter the lesser sac and spread to the transverse mesocolon, phrenocolic ligament, and small bowel mesentery, causing serosal inflammation and irritation of the gastrointestinal tract.^{55,61,68} Thickening and spiculation of mucosal folds in the stomach and duodenum can be seen on CT and barium studies. Varying degrees of atony associated with spastic segments of the duodenum, jejunum, and transverse colon can also be present.⁶⁸⁻⁷¹

Cholangiography

ERCP is generally not performed during an acute episode of pancreatitis because it may exacerbate the inflammation or introduce an infection. The pancreatic duct is usually normal but can be compressed. Some gastroenterologists advocate ERCP with sphincterotomy to alter the course of pancreatitis when it appears that multiple stones are passing through the common bile duct. ERCP can also demonstrate other causes of pancreatitis, such as pancreas divisum, choledochocoele, choledochal cyst, perivaterian duodenal diverticulum, pancreatic or

bile duct carcinoma, and ampullary carcinoma¹⁵ (see Chapter 74). Magnetic resonance cholangiopancreatography (MRCP) is often preferred to investigate the cause of pancreatitis, however, avoiding the complications associated with ERCP.^{72,73}

Angiography

Angiography is usually not performed in patients with acute pancreatitis unless the presence of a pseudoaneurysm that could be treated with transcatheter embolization is suspected. It can also be helpful to elucidate vascular causes of pancreatitis, such as vasculitis, polyarteritis nodosum, post-aortic aneurysm resection, after transplantation, Ortner's syndrome, systemic lupus erythematosus, low-flow states, shock, and diabetes.⁷⁴⁻⁷⁶

Ultrasonography

Abnormal findings are seen at sonography in 33% to 90% of patients with acute pancreatitis.⁷⁷ The classic sonographic appearance in pancreatitis is a diffusely enlarged hypoechoic pancreas.⁷⁸⁻⁸⁰ Less commonly, focal enlargement is present. The echogenicity of the pancreas in acute pancreatitis is extremely variable and depends on a number of factors: the timing of the sonographic study, with maximal decrease in echogenicity occurring 2 to 5 days after the initial episode of acute abdominal pain; the amount of intrapancreatic fat (with age, the pancreas is replaced by fat and hence becomes more echogenic); the presence of hemorrhage; the presence of underlying chronic pancreatitis with calcification; and the degree of extrapancreatic spread of acute pancreatitis.^{78,79,81} Echogenicity is also subjective because the usual internal standard used to gauge pancreatic texture is the liver, which often has altered architecture caused by fatty infiltration, cirrhosis, or alcoholic pancreatitis. Similarly, size changes are difficult to assess without a baseline scan because the overall volume of the gland is variable and diminishes with advanced age.⁸²

Figure 97-2 Anatomic relationships of the pancreas. These relationships explain the radiographic findings on plain films, barium studies, and cross-sectional images. **A.** Sagittal diagram of the abdomen depicts avenues of spread of the inflammation and fluid of acute pancreatitis: (1) spread into the lesser sac will deform the posterior gastric wall; (2) spread into the transverse mesocolon will cause deformity along the inferior border of the colon; (3) spread into the root of the small bowel mesentery will cause deformity of the small bowel loops; (4) extension into the duodenum will cause deformity and mucosal abnormalities; (5) spread into the remainder of the retroperitoneum will cause changes in the anterior pararenal space. *D*, Duodenum; *L*, lung; *P*, pancreas; *S*, spleen; *SBM*, small bowel mesentery; *TC*, transverse colon. **B.** Axial diagram shows the intimate relationship between the pancreas and other structures in the anterior pararenal space (duodenum, ascending and descending colon). The kidneys lie in the perirenal space. *Ao*, Aorta; *IVC*, inferior vena cava.

The pancreatic duct may dilate, particularly if the inflammation is confined to the pancreatic head. Focal intrapancreatic masses may be due to an acute fluid collection, hemorrhage, or ill-defined and hypoechoic pancreatic enlargement that may sonographically simulate carcinoma. Cystic masses should be scrutinized with Doppler ultrasound studies to exclude pancreatic pseudoaneurysms.⁸³ Lesser sac fluid collections are often seen and may produce a “butterfly” appearance.⁸⁴

The foregoing discussion assumes that the pancreas is well visualized. In acute pancreatitis, bowel gas and other factors will limit visualization of the gland in one fourth to one third of patients. This is one of four major limitations of ultrasound in this clinical setting. The second is the inability of ultrasound to completely define the complex extrapancreatic spread of inflammation along fascial planes and within the peripancreatic compartments. It is particularly limited in visualizing spread into the transverse mesocolon. Third, ultrasound cannot specifically reveal areas of pancreatic necrosis in patients with severe pancreatitis, information that provides important insights into the ultimate prognosis of necrotizing pancreatitis. Finally, only CT, MRI, or angiography can diagnose many gastrointestinal and vascular complications of acute pancreatitis.^{78,79}

What, then, is the role of sonography in acute pancreatitis? It is a good screening test in patients with suspected biliary pancreatitis and a mild clinical course. It is helpful to detect gallstones, for which CT is not effective.⁸⁵⁻⁸⁷ It is also useful in thin patients with mild edematous pancreatitis that promptly responds to conservative therapy. Ultrasound has limitations in the detection of distal common duct stones. It also has limitations in the diagnosis of necrosis. Ultrasound may be used to assess the presence or absence of solid necrotic material and to differentiate it from cystic material to help guide drainage when it is being considered. CT is preferred for patients with clinically severe pancreatitis; those whose disease fails to respond to conservative therapy; acutely ill patients who pose diagnostic dilemmas; and patients with complications, such as infected pseudocyst, hemorrhage, pseudoaneurysm formation, and pancreatic necrosis.^{88,89}

The use of tissue harmonic imaging improves image quality, delineation of the pancreatic tail, lesion conspicuity, and fluid-solid differentiation relative to conventional B-mode sonography.^{90,91} Tissue harmonic sonography was able to detect abnormalities in 91% of patients with acute pancreatitis.⁹² The authors found that the two most useful sonographic findings were extrapancreatic inflammation and parenchymal inhomogeneity. It was difficult, however, to distinguish between fluid collections and extrapancreatic inflammation. Nevertheless, the accuracy of CT is still superior to that of tissue harmonic sonography in the evaluation of acute pancreatitis, as even with tissue harmonics, sonography does not demonstrate necrosis or other complications as well as CT does.

Computed Tomography and Magnetic Resonance Imaging

CT is the premier imaging test in the diagnosis and management of patients with acute pancreatitis. It visualizes the gland, the bowel, the retroperitoneum, the abdominal ligaments, the mesenteries, and the omentum in their entirety. In addition, it may help determine the etiology, stage severity, and detect complications of pancreatitis; it can be used to guide interventional procedures, such as fine-needle aspiration biopsy or catheter placement. However, the radiation dose delivered by CT may be a significant factor for young patients with pancreatitis requiring multiple examinations. MRI may be an option for these patients; however, it is more costly than CT. Other advantages of MRI include its high soft tissue contrast resolution and ability to evaluate the common bile duct, pancreatic duct, and parenchyma in a single examination.⁹³⁻⁹⁶ Before the awareness of nephrogenic systemic fibrosis, contrast-enhanced MRI could be used in patients with renal insufficiency when

contrast-enhanced CT could not be performed. MRI, however, is limited in the more acute setting when the patient is very ill, as patients need to be able to hold the breath and be relatively stable for the longer examination. MRI may be helpful to distinguish peripancreatic fluid collections as solid debris from cystic collections and show the compositions of pseudocysts better than multidetector CT (MDCT).^{39,97-100} Diffusion-weighted MRI can be helpful in the diagnosis of acute pancreatitis.¹⁰¹

CT Technique. The technique used in evaluating patients with pancreatitis should be individualized. The best diagnostic images are obtained with MDCT by achieving optimal vascular and parenchymal enhancement and avoiding respiratory motion. A rapid 5 mL/s intravenous bolus of 150 mL of 60% nonionic contrast material is injected. We routinely use a two-phase imaging technique. Images in the pancreatic and hepatic venous phases are obtained with 2- to 3-mm slice thickness. In addition, unenhanced images may be helpful through the pancreas. Images can be reconstructed into any plane with various thickness and section intervals at any level in the scanned volume.

MRI Technique. The role of MRI has become increasingly more important with the advent of high-field-strength imaging, phased-array surface coils, MR-compatible power injectors, rapid gradient-echo breath-hold techniques, and fat suppression.^{96,102,103} These technologic advances allow faster sequences with high-resolution images that are largely free of artifacts. T1-weighted fat-suppressed sequences before and after gadolinium administration and T2-weighted sequences are essential for pancreatic evaluation. The T1-weighted fat-suppressed sequences are able to detect focal or diffuse abnormalities in the pancreas and to delineate the peripancreatic fat planes. With T1 relaxation time shorter than that of the liver, the normal pancreas has the highest signal intensity of intra-abdominal organs. This is attributed to the abundance of acinar proteins, endoplasmic reticulum, and paramagnetic ions within the pancreas.^{104,105} Contrast-enhanced T1-weighted images in the arterial phase show intense enhancement of the normal pancreas, which becomes less intense on subsequent phases. T2-weighted sequences show fluid as high signal intensity, allowing assessment of the pancreaticobiliary ducts and detection of fluid collections and peripancreatic edema.

Diagnosis. The imaging findings in acute pancreatitis are similar, regardless of etiology, with the exception of traumatic pancreatitis, in which pancreatic lacerations cause high-density (50-90 HU) hematomas. MRI can be helpful in determining the etiology of pancreatitis, including choledocholithiasis, pancreas divisum, and underlying tumors. In the acute setting, however, the etiology may be difficult to determine because of the significant inflammation, which may obscure stones, pancreaticobiliary ducts, or underlying masses.

In mild forms of pancreatitis, CT and MRI may show normal findings or a slight to moderate increase in the size of the pancreas. Mild inflammation may surround an otherwise normal-appearing gland (Fig. 97-3). Alternatively, the pancreas may be diffusely enlarged, with shaggy and irregular contour, and slightly heterogeneous parenchyma, which enhances less than normal (Fig. 97-4). On MRI, there may be decreased pancreatic signal intensity on T1-weighted fat-suppressed sequences before

Figure 97-3 Acute pancreatitis. Axial contrast-enhanced MDCT image shows peripancreatic inflammatory changes (arrows) in a patient with abdominal pain and elevated amylase levels. The pancreas (P) has normal size and enhancement.

Figure 97-4 Mild acute pancreatitis. Axial arterial phase contrast-enhanced MDCT image shows diffuse enlargement and decreased enhancement of the pancreas. Note peripancreatic inflammatory changes (arrows). P, Pancreas.

and after gadolinium administration, depending on the degree of inflammation and edema (Fig. 97-5).^{96,106}

In more advanced cases, extravasation of pancreatic fluid leads to the formation of intrapancreatic and extrapancreatic fluid collections (Fig. 97-6). Because the pancreas does not have a well-developed fibrous capsule, pancreatic secretions commonly extravasate in the retroperitoneum, most often in the anterior pararenal space (Fig. 97-7; see also Fig. 97-1). CT superbly depicts peripancreatic inflammation, fluid, and occasionally mild thickening of the adjacent fascial planes (see Figs. 97-1 and 97-3). Peripancreatic inflammatory stranding is also well seen on MRI (see Fig. 97-5).

A more unusual segmental form of acute pancreatitis occurs in as many as 18% of patients.^{14,88} The CT findings are similar to those in diffuse pancreatitis; however, only part of the gland is involved either exclusively or predominantly. The segment most often involved is the pancreatic head. This form of pancreatitis is usually mild and is most often associated with stone

Figure 97-5 Mild ERCP-induced pancreatitis. **A.** Axial T2-weighted half-Fourier acquisition single-shot turbo spin-echo (HASTE) MR image shows peripancreatic fluid (arrows) with high signal intensity. The pancreas also has mildly increased signal intensity due to edema. **B.** Axial T1-weighted fat-suppressed spoiled gradient-echo MR image shows normal high signal intensity of the pancreas in this patient with uncomplicated pancreatitis. The peripancreatic fluid is better seen on T2-weighted images. **C.** The pancreas shows diffusely decreased enhancement during the arterial phase after administration of gadolinium. (A-C from Miller FH, Keppke AL, Dalal K, et al: *MRI of pancreatitis and its complications: Part 1, acute pancreatitis*. AJR Am J Roentgenol 183:1637–1644, 2004. Reprinted with permission from the American Journal of Roentgenology.)

disease.^{6,98,107} However, patients with segmental pancreatitis should be carefully evaluated to exclude the less common possibility of adenocarcinoma simulating pancreatitis or a mass leading to pancreatitis (Figs. 97-8 and 97-9). It may be appropriate to further investigate these patients with EUS, MR, ERCP, or biopsy or to perform short-term follow-up CT or MRI, especially if they are older or do not have risk factors for pancreatitis.¹⁰⁶

In severe forms of necrotizing pancreatitis, the gland may become enlarged, and it is commonly enveloped by high-attenuation heterogeneous fluid collections. Because of

Figure 97-6 ERCP-induced pancreatitis with peripancreatic fluid collections. Axial enhanced T1-weighted fat-suppressed spoiled gradient-echo MR image shows heterogeneous pancreatic enhancement and peripancreatic fluid and inflammation (straight arrows). Fluid (curved arrow) is seen between the pancreas and the splenic vein. P, Pancreas. (From Miller FH, Keppke AL, Dalal K, et al: *MRI of pancreatitis and its complications: Part 1, acute pancreatitis*. AJR Am J Roentgenol 183:1637–1644, 2004. Reprinted with permission from the American Journal of Roentgenology.)

high-attenuation exudates, the presence of pancreatic necrosis cannot be assessed on CT unless the gland is imaged during the late arterial–early portal venous phase of a rapid bolus intravenous injection of contrast medium (Fig. 97-10).⁷⁷ On MRI, peripancreatic high signal intensity may be seen on T1-weighted fat-suppressed sequences related to fat necrosis and hemorrhage (Fig. 97-11). This finding has been associated with a worse prognosis.¹⁰⁸ Patchy areas of absence of enhancement, fragmentation, and liquefaction necrosis can be detected on CT or MRI (Fig. 97-12). Poorly defined peripancreatic exudates obliterate the peripancreatic fat, envelop the pancreas, dissect fascial planes, and penetrate through fascial and peritoneal boundaries and ligaments. These collections most often occur in the anterior pararenal space around the body and tail of the pancreas and within the lesser peritoneal sac (Fig. 97-13).¹⁰⁹ Penetration through Gerota's fascia with involvement of the perirenal fat and kidneys occurs rarely. When fluid collections are massive, they tend to extend inferiorly along the pararenal spaces in the left flank or bilaterally. They can course over the psoas muscle, enter the pelvis (see Fig. 97-13B), and sometimes extend into the groin. Exudates can invade the small bowel mesentery, the transverse mesocolon, and the posterior pararenal spaces (see Fig. 97-7). Fluid can penetrate into solid organs, such as the spleen or the liver, and even the mediastinum. Splenic involvement is most common because of the close anatomic relationship of the pancreatic tail and splenic hilum. Subcapsular or intrasplenic fluid collections or pseudocysts, infarcts, and splenic hemorrhage may be seen with pancreatitis.

In about 7% to 12% of patients with acute pancreatitis, CT or MRI reveals free intraperitoneal fluid, usually in small volumes. Massive pancreatic ascites, caused by communication of a disrupted pancreatic duct with the peritoneal cavity, is rarely seen.^{30,110} This presentation is usually associated with a more severe form of pancreatitis. In most of these patients, characteristic pancreatic and peripancreatic abnormalities are recognized. Rarely, pancreatic ascites can develop in patients

Figure 97-7 Acute pancreatitis with peripancreatic fluid. **A.** Axial contrast-enhanced MDCT image shows normal pancreatic enhancement and diffuse peripancreatic fluid and stranding. P, Pancreas. **B.** The pancreatic head (P) is enlarged. Fluid is seen extending into the perirenal and anterior pararenal spaces and into the transverse mesocolon and mesentery. **C.** Specimen from a different patient, with fat necrosis of the greater omentum due to acute pancreatitis.

Figure 97-8 Pancreatic cancer mimicking acute pancreatitis. **A.** Axial contrast-enhanced MDCT image shows stranding surrounding pancreatic tail (short arrow) and gallstone (long arrow) in this patient with uncontrollable back pain who was believed to have pancreatitis. **B.** Six months after cholecystectomy, the patient had persistent pain. His amylase and lipase levels were only mildly elevated. Axial contrast-enhanced MDCT image shows a pancreatic tail mass (arrow) that encases vessels and was proved to be adenocarcinoma.

with a normal-appearing gland on CT scans. In these patients, paracentesis with amylase determination is needed to make the diagnosis.¹¹¹ The treatment of pancreatic ascites includes conservative management with nasogastric suction, parenteral nutrition, and repeated paracenteses.^{112,113} If these measures fail, interventional or surgical procedures, including pancreatic duct stenting, pancreaticojejunostomy, and distal pancreatectomy, may be required.

Diagnostic Sensitivity. The accuracy of CT in the diagnosis of acute pancreatitis depends to a large extent on the severity of the disease. The reported CT sensitivity for the diagnosis of acute pancreatitis ranges from 77% to 92%.^{51,114,115} The usefulness of CT is further supported by its high specificity. In most series, there are few false-positive findings, and CT specificity as high as 100% has been reported.¹¹⁴ In addition, by examining

the entire abdomen, CT can reveal a variety of other abdominal conditions in patients clinically suspected of having acute pancreatitis.

Limitations in Diagnosis. Limitations in the CT diagnosis of acute pancreatitis are related to suboptimal examinations resulting from poor technique, lack of intravenous contrast medium, or inability of the patient to cooperate. Motion or streak artifacts and paucity of retroperitoneal fat are limiting factors in some patients. In addition, in mild forms of clinical pancreatitis, morphologic parenchymal or retroperitoneal abnormalities do not develop and the gland may appear normal on CT scans. It occurs in patients with mild symptoms and transitory elevation of serum amylase concentration. The incidence of normal CT scans in these persons is not well established because surgical or pathologic correlation is lacking, but

it has been estimated to be 14% to 28%.^{88,116} Experience has shown that given a good-quality CT scan, all patients with moderate or severe pancreatitis will exhibit some CT abnormality. In patients with normal results of CT examination, pancreatitis is either absent or of minimal clinical significance.

Staging. By virtue of its ability to accurately and rapidly evaluate the pancreas, peritoneum, and retroperitoneum, CT can be used to predict the severity of acute pancreatitis.^{40,117-126} The revision of the Atlanta classification addresses the lack of uniformity between referring physicians and diagnostic radiologists in describing the terms related to acute pancreatitis.^{10,11} The classification addresses fluid collections before and after 4 weeks of the onset of symptoms by the presence or absence of necrosis and by the presence or absence of infection.

Grading System. The CT severity index (CTSI), developed by Balthazar and colleagues, focused on the presence and degree of pancreatic inflammation and necrosis to predict morbidity

and mortality in patients with acute pancreatitis. In 2004, Morte and coworkers⁴⁰ modified the index with improved correlation with patient outcomes. The modified scale ascribes points to degrees of pancreatic inflammation.

Grade A: normal pancreas

Grade B: focal or diffuse enlargement of the gland including contour irregularities and inhomogeneous attenuation but without peripancreatic inflammation

Grade C: intrinsic pancreatic abnormalities associated with inflammatory changes in the peripancreatic fat (see Figs. 97-4 and 97-5)

Grade D: small and usually single, ill-defined fluid collection

Grade E: two or more large fluid collections or the presence of gas in the pancreas or retroperitoneum (Fig. 97-14)^{88,119}

In cases of pancreatic necrosis, points are given for certain degrees of necrosis, with more than 30% necrosis receiving the maximum 4 points. Two points are given for cases that involve extrapancreatic complications. The numerical modified CTSI

Figure 97-9 Pancreatic cancer mimicking pancreatitis. Axial contrast-enhanced MDCT image shows enlargement and lack of enhancement of the body and tail of the pancreas (P), mimicking pancreatic necrosis. Note peripancreatic stranding and soft tissue density (short arrows) surrounding the celiac artery, raising suspicion for cancer. There was thrombosis of the superior mesenteric vein, splenic vein, and extrahepatic portal vein (long arrow). Histologic examination revealed pancreatic adenocarcinoma.

Figure 97-11 Pancreatitis with the development of high signal intensity fluid collections. Axial T1-weighted fat-suppressed spoiled gradient-echo MR image shows complex peripancreatic fluid collection (arrows) with predominantly high signal intensity, which extended inferiorly from the level of the pancreatic head (P). Aspiration biopsy revealed a necrotizing inflammatory process.

Figure 97-10 Gallstone pancreatitis with necrosis. **A.** Axial nonenhanced MDCT image shows an enlarged pancreas (P) with indistinct borders because of peripancreatic inflammatory changes (solid arrows). Gallstone (open arrow) is seen in the gallbladder neck. **B.** Axial arterial phase contrast-enhanced MDCT image shows lack of enhancement of the pancreas (P), consistent with necrosis.

has a maximum of 10 points and is the sum of inflammation points, pancreatic necrosis points, and extrapancreatic complication points.⁴⁰

Mortele and coworkers⁴⁰ modified the CTSI as the score obtained did not significantly correlate with the development of complications and demonstrated significant interobserver variability in scoring. Moreover, Balthazar and colleagues found no significant difference in morbidity and mortality in differentiating between 30% to 50% necrosis and more than 50% necrosis. The modified CTSI condenses the scoring for necrosis to differentiate above and below 30% and also gives points for extrapancreatic complications.⁴⁰

Delineation of Necrosis. During the arterial phase of bolus intravenous administration of contrast medium, the normal pancreas should enhance homogeneously. Mild inflammation

and interstitial edema do not interfere with the expected homogeneous enhancement of the gland (see Figs. 97-1 and 97-3). When necrosis is present, there is absence of contrast medium enhancement together with liquefaction and a change in the density or signal intensity of the gland (Figs. 97-15 and 97-16). Gadolinium-enhanced T1-weighted gradient-echo MR images demonstrate pancreatic necrosis as low signal areas of nonenhancing parenchyma (Fig. 97-17). The process can be focal or segmental or can affect the entire pancreatic gland and may involve the peripancreatic tissue in combination with the pancreas or separately (see Figs. 97-15 to 97-17).^{122,127,128} In the original series of Kivisaari and associates^{129,130} using CT, mild pancreatitis was associated with a rapid rise in the density of the gland by 40 to 50 HU after administration of contrast material. Pancreatic necrosis was found at surgery in all patients who exhibited absence of enhancement or low enhancing values of

Figure 97-12 Acute pancreatitis with necrosis evolving into walled-off necrosis. **A.** Axial contrast-enhanced MDCT image shows patchy, confluent necrotic areas (arrow) in pancreatic body and tail. Note peripancreatic inflammatory stranding. **B.** Axial contrast-enhanced MDCT image 4 months after the initial episode of pancreatitis shows the development of walled-off necrosis (arrows) in previously necrotic body and tail of pancreas.

Figure 97-13 Pancreatitis with acute fluid collections. **A.** Axial contrast-enhanced MDCT image shows heterogeneous fluid collection (arrows) in the left anterior pararenal space involving the tail of the pancreas. Note that the fluid collection does not spread beyond Gerota's fascia. This collection extended inferiorly along the left pericolic gutter into the pelvis. **B.** Coronal contrast-enhanced MDCT image from another patient with pancreatitis shows fluid (arrows) extending inferiorly from the pancreatic region along the interfascial planes into the pelvis. The pathway of fluid is better demonstrated on coronal reformatted images.

less than 30 HU (see Figs. 97-15 and 97-16). Other investigators have corroborated the CT-surgical correlation in the detection of pancreatic necrosis.^{131,132} In a series of 93 patients, an overall CT accuracy of 85% with 100% sensitivity for extensive glandular necrosis was found.¹²⁸ At times, MRI may be more

Figure 97-14 Infected necrosis. Axial contrast-enhanced MDCT image shows absence of normal enhancing pancreatic parenchyma. There are air bubbles and debris (arrows) in the pancreatic bed suggesting infected necrosis. The patient underwent pancreatic débridement.

Figure 97-15 Acute necrotizing pancreatitis with acute necrotizing collections in the pancreas and peripancreatic tissues. Axial contrast-enhanced MDCT image shows necrosis of the entire pancreas and peripancreatic necrosis.

sensitive than CT for the detection of pancreatic necrosis because of the greater sensitivity of MRI to gadolinium than of CT to iodinated contrast agents. Many patients with pancreatic necrosis, however, may be seriously ill and may be unable to hold the breath for the required MRI sequences.

In Balthazar's series, there was good correlation between necrosis and length of hospitalization, development of complications, and death; patients without necrosis had no mortality and only 6% morbidity, whereas patients with necrosis exhibited 23% mortality and 82% morbidity.^{119,122} The degree of necrosis also was important. Patients with small areas of necrosis (<30%) showed no mortality and 40% morbidity, whereas large areas of necrosis (≥50%) were associated with 75% to 100% morbidity and 11% to 25% mortality. The combined morbidity of patients with more than 30% necrosis was 94%, and the mortality was 29%. There was no significant difference in prognosis between patients with up to 50% necrosis and those with more than 50% necrosis. Other studies have shown that infected pancreatic necrosis is also a significant predictor of organ failure and mortality in acute pancreatitis.^{90,133,134} Garg⁹⁰ found a mortality rate of 12% for patients with sterile necrosis and 50% for those with infected necrosis.

Indications for Examination. Many patients with acute interstitial edematous pancreatitis have typical clinical presentations and show rapid amelioration with limited supportive therapy. They do not require imaging examinations for diagnosis or management. On the other hand, CT imaging is needed and should be performed early when the clinical diagnosis is in doubt; there is failure to respond to medical treatment within 48 to 72 hours; acute abdominal symptoms (distention, tenderness), leukocytosis, or fever is present; patients have organ failure or signs of severe acute pancreatitis; and there is a change in clinical status suggesting a developing complication. Specific indications for performing MRI over CT include allergy to iodinated contrast agents; to detect the etiology of pancreatitis, such as choledocholithiasis, pancreas divisum, and pancreatic tumors; and to characterize complex fluid collections as liquefied or necrotic and to determine their drainability.

COMPLICATIONS

Local complications after acute pancreatitis include acute peripancreatic fluid collections, pseudocysts, acute necrotic collection, and walled-off necrosis.¹⁰ The prompt detection and treatment of local complications are essential because they are responsible for more than 50% of the mortality associated with acute pancreatitis.^{31,135-137}

Fluid Collections and Pseudocysts

Acute pancreatic fluid collections are generally seen within the first 4 weeks and pseudocysts after 4 weeks. Acute pancreatic fluid collections characteristically do not have a solid component, lack a discrete wall, and are located near the pancreas (see Fig. 97-13). Fluid collections develop in up to 50% of patients with acute pancreatitis within the first few days of pancreatitis. The fluid may be pancreatic juice, serum, or blood. They develop either from actual rupture of the pancreatic duct with liberation of enzymes and pancreatic juice or secondary to exudation of fluid from the surface of the pancreas due to activation of pancreatic enzymes within the gland. The fluid is contained by whatever structures happen to be adjacent to the collection. Most fluid collections are absorbed within 2 to 3 weeks. Drainage or aspiration is generally avoided to prevent introduction of infection unless it is thought to be a rare infected acute pancreatic fluid collection. Unresorbed fluid collections can organize and, within 4 to 6 weeks, develop a fibrous capsule, forming a pseudocyst.^{30,138} The lack of resorption of extravasated secretions and a communicating tract with the pancreatic ductal system are implicated in the development of pseudocysts.

Figure 97-17 Pancreatitis with necrosis involving more than 50% of the gland. Axial gadolinium-enhanced T1-weighted fat-suppressed spoiled gradient-echo MR image shows nonenhancing necrotic areas (arrows) in the body and tail of the pancreas. (From Ly JN, Miller FH: MR imaging of the pancreas: A practical approach. *Radiol Clin North Am* 40:1289–1306, 2002.)

When an acute pancreatic fluid collection becomes encapsulated by a fibrous wall more than 4 weeks after symptom onset, it is referred to as a pseudocyst. Pseudocysts often resolve spontaneously when they lose communication with the pancreatic duct. Pseudocysts develop during the initial attack of pancreatitis in 1% to 3% of patients.^{88,139,140} They have been reported to occur in 12% of patients after several episodes of alcoholic pancreatitis.¹⁶ The main causes of pancreatic pseudocysts are chronic alcoholism (75%) and abdominal trauma (13%), with cholelithiasis, pancreatic carcinoma, and idiopathic causes composing the remainder.¹⁴¹ If the patient with a suspected pseudocyst has no history of pancreatitis, pancreatic trauma, or pancreatic surgery, a follow-up imaging study or aspiration biopsy may be required to exclude a pancreatic cystic neoplasm.¹³⁸

The clinical significance of a pseudocyst is related to its size and the potentially lethal complications that may occur. Pseudocysts displace and compress adjacent abdominal organs and can produce obstruction, pain, and jaundice. Spontaneous rupture in the peritoneal cavity leads to pancreatic ascites or peritonitis. Erosion into an adjacent vessel leads to massive and sudden hemorrhage. Most of these complications, however, occur in pseudocysts larger than 4 to 5 cm. Small pseudocysts, often revealed by CT in asymptomatic patients, have a low incidence of morbidity and can be observed expectantly with clinical and CT examinations.^{30,43} Surgical, endoscopic, or percutaneous drainage is indicated for pseudocysts that increase in size, become symptomatic, or develop complications.^{30,42,142} The development of percutaneous and endoscopic techniques offers an alternative means of drainage of pseudocysts that is less invasive.^{142,143} Success rates of more than 90% have been reported with percutaneous drainage of pseudocysts guided by CT or sonography.^{142,144} Percutaneous drainage techniques of pancreatic fluid collections are discussed in Chapter 95.

Pseudocysts vary greatly in size and are generally round or oval. On CT scans, they are characterized by low fluid density (<15 HU) contents and by a peripheral fibrous capsule. Higher attenuation values are indicative of secondary infection or the presence of necrotic tissue. Hounsfield unit values greater than 40 to 50 are suggestive of intracystic hemorrhage. On MRI, uncomplicated pseudocysts typically show low signal intensity on T1-weighted sequences and high signal intensity on T2-weighted sequences. Complicated pseudocysts may present high signal intensity on T1-weighted images because of hemorrhagic or proteinaceous fluid and may contain solid debris; these are best depicted on T2-weighted images (Figs. 97-18 and 97-19). MRI is superior to other imaging modalities to

Figure 97-18 Pancreatitis with hemorrhagic pseudocyst. A. Axial T1-weighted fat-suppressed spoiled gradient-echo MR image shows pseudocyst (arrow) in the pancreatic tail with high signal intensity from hemorrhagic content. **B.** Axial T2-weighted HASTE MR image shows low signal intensity rim of hemosiderin in pseudocyst (arrow). The diagnosis of hemorrhage is easily made on MRI because of the hemosiderin rim. (A and B from Miller FH, Keppke AL, Dalal K, et al: MRI of pancreatitis and its complications: Part 1, acute pancreatitis. *AJR Am J Roentgenol* 183:1637–1644, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 97-19 Pancreatic pseudocyst with internal debris. **A.** Axial contrast-enhanced MDCT image shows hypodense fluid collections in the pancreatic tail (*short arrow*) and in the lesser sac (*long arrow*), consistent with pseudocysts. **B.** Axial contrast-enhanced T1-weighted fat-suppressed spoiled gradient-echo MR image obtained 1 day after CT shows hypointense pseudocyst (*short arrow*) in the pancreatic tail and moderate signal intensity pseudocyst (*long arrow*) in the lesser sac. Note associated peripancreatic inflammatory changes. **C.** Axial T2-weighted HASTE image shows debris (*arrow*) inside the intrapancreatic pseudocyst that was not seen on CT. Note large amount of ascites in this patient with end-stage renal failure.

Figure 97-20 Acute pancreatitis with pancreatic duct rupture and pseudocyst. Thick-slab T2-weighted rapid acquisition and relaxation enhancement (RARE) MRCP image shows disrupted pancreatic duct (*short arrow*) and peripancreatic pseudocyst (*long arrow*) containing low signal intensity debris. (From Ly JN, Miller FH: *MR imaging of the pancreas: A practical approach*. Radiol Clin North Am 40:1289–1306, 2002.)

characterize the content of fluid collections, which may have prognostic and therapeutic significance.^{98,145}

ERCP is less effective than CT or MRI in showing pseudocysts as less than 50% of pseudocysts fill with contrast material at ERCP. Conversely, MRCP is able to detect pseudocysts that do not communicate with the pancreatic duct. ERCP, however, may be required to demonstrate communication between a pseudocyst and the pancreatic duct, although sometimes it can be seen on MRI (Fig. 97-20). Communicating pseudocysts may require prolonged catheter drainage until the communication

to the pancreatic duct closes and the cyst collapses. Decompression of concomitant pancreatic duct obstruction may be required.

Although many of the initial poorly defined fluid collections seen in acute pancreatitis resolve spontaneously, the natural history of a pseudocyst is difficult to predict. They may persist, they can resolve, or they can even continue to grow over time. Spontaneous resolution (Fig. 97-21) even of large pseudocysts can occur and is explained by drainage into the pancreatic duct, erosion into an adjacent hollow organ (stomach, small bowel, colon), or rupture with spillage into the peritoneal cavity.

Pancreatic Necrosis

Acute necrotic collection and walled-off necrosis are the terms for local complications of acute necrotizing pancreatitis. Acute necrotic collections, which contain different amounts of fluid and necrotic material, form within 4 weeks of the onset of acute pancreatitis symptoms. They occur only in the setting of acute necrotizing pancreatitis and lack a definable wall. They may be intrapancreatic or extrapancreatic. Walled-off necrosis, a persistent heterogeneous collection (solid and liquefied) with an enhancing thick inflammatory wall, usually develops after 4 weeks of the onset of necrotizing pancreatitis (Figs. 97-22 to 97-24). It may be intrapancreatic or extrapancreatic and may be single or multiple.

The diagnosis of infected necrosis of an acute necrotic collection or walled-off necrosis can be suspected by the patient's clinical findings or presence of gas within a fluid collection. On CT, sterile, partially liquefied pancreatic necrosis cannot be differentiated from infected necrosis unless gas bubbles, seen in about 12% to 18% of cases, are present in the necrotic tissue (see Fig. 97-14).³⁰ In the absence of gas, if required, a percutaneous aspiration for Gram stain and culture could be performed.^{30,140,141,146} Recent series suggest that the large majority of patients do not require fine-needle aspiration, especially if

Figure 97-21 Spontaneous rupture of a pseudocyst into the stomach. **A.** The patient had a documented large pseudocyst scheduled to be surgically drained. CT examination before elective surgery shows decompression of the pseudocyst into the stomach (S) (arrows). P, Pancreas. **B.** Upper gastrointestinal examination reveals an ulceration (arrow) consistent with spontaneous drainage of a pseudocyst.

Figure 97-22 Patient with walled-off necrosis. Gadolinium-enhanced T1 fat-suppressed image shows heterogeneous encapsulated collection in the pancreas with nonliquid areas of debris.

percutaneous drainage is part of management.^{10,147} Management of pancreatitis is discussed in Chapter 95.

Infected Pseudocysts

Fluid collections that fail to be resorbed represent an ideal medium for bacterial growth, explaining the development of abscesses, now referred to as infected pseudocysts per the revised Acute Pancreatitis Classification Working Group. In the past, abscesses were considered the major cause of death in acute pancreatitis.^{115,148} The associated high mortality was related mainly to significant delays in diagnosis. They develop within several weeks after the onset of symptoms in patients with severe forms of pancreatitis. Their presence is usually heralded by deterioration in the clinical course with septic systemic symptoms. They may have an inconspicuous clinical presentation initially.¹⁴⁹

Infected pseudocysts are located in the peripancreatic tissues and have different sizes and configurations. On CT scans, they appear as poorly defined or partially encapsulated fluid collections of different densities (20-50 HU) and are often

indistinguishable from residual noninfected fluid collections.⁸⁸ A more characteristic appearance, seen in about 20% of infected pseudocysts, is the presence of gas bubbles produced by gas-forming bacteria. Retroperitoneal gas may be seen in patients with enteric fistulas; however, it is always strongly suggestive of an infection.^{8,13,150} CT is more sensitive than MRI for detection of small gas bubbles, although large collections of gas or gas-fluid levels can be detected on MRI and are best seen on T2-weighted images. CT is accurate in revealing small collections of retroperitoneal fluid and gas and depicting location and extent. This finding quickly identifies a potential life-threatening complication. Infection should be suspected in all patients with pancreatitis in whom poorly encapsulated fluid collections are still present 2 to 4 weeks after the initial attack. MRI may be able to differentiate infected collections with complex internal content from simple collections in these patients (see Fig. 97-24). The use of diffusion-weighted MRI may be helpful. If the diagnosis is in doubt, ultrasound-guided or CT-guided needle aspiration can rapidly and reliably establish the diagnosis, contributing greatly to the early detection, treatment, and decreased mortality in this group of patients.^{142,143,151,152} Percutaneous drainage is the therapeutic procedure of choice for infected pseudocysts.¹⁵³⁻¹⁵⁵

Hemorrhage

Although small patchy areas of hemorrhage combined with necrotic tissue are common findings in acute pancreatitis, massive life-threatening intra-abdominal hemorrhage is seldom reported. This complication may occur within 2 to 3 weeks to several years after an acute episode of pancreatitis.¹⁵⁶⁻¹⁵⁸ It is the result of erosion of peripancreatic vessels with the formation of a pseudoaneurysm and subsequent retroperitoneal bleeding. Commonly, the site of bleeding is along the pancreaticoduodenal arcade or along the splenic vessels adjacent to the tail of the pancreas. Pseudoaneurysms can be located within a pancreatic pseudocyst. Hemorrhage occurs when a slowly enlarging pseudoaneurysm ruptures into the peritoneum or erodes into an adjacent hollow viscus or into the pancreatic duct, producing hemosuccus pancreaticus.¹⁵⁸ CT examination can identify retroperitoneal bleeding by the presence of high-density (50-100 HU) fluid collections. MRI is more sensitive for hemorrhage, which is depicted as high signal intensity on

Figure 97-23 Walled-off necrosis and pseudoaneurysm development. **A.** Axial contrast-enhanced MDCT shows extensive pancreatic necrosis with lack of enhancement of the body and tail of the pancreas. **B.** Axial contrast-enhanced MDCT 6 weeks later shows walled-off necrosis with fluid collection and development of thickened wall. Free air is seen from surgery. **C.** Axial contrast-enhanced MDCT 2 months later shows development of pseudoaneurysm (arrow), which was subsequently embolized.

Figure 97-24 Pancreatitis with infected walled-off necrosis. **A.** Axial contrast-enhanced MDCT image shows hypodense fluid collection (arrow) in the pancreatic head suggestive of walled-off necrosis in this patient with pancreatitis. **B.** Axial gadolinium-enhanced T1-weighted fat-suppressed spoiled gradient-echo MR image obtained 11 days after CT shows an air bubble (arrow) within the walled-off necrosis suggestive of infected walled-off necrosis. **C.** Coronal T2-weighted HASTE MR image shows low signal intensity debris (curved arrow) within the pancreatic abscess that was not seen on CT. The presence of necrotic debris was confirmed at surgery. A, Abscess, now referred to as infected walled-off necrosis on the basis of the revised Acute Pancreatitis Classification Working Group. S, Stomach. (B and C from Miller FH, Keppke AL, Dalal K, et al: MRI of pancreatitis and its complications: Part 1, acute pancreatitis. *AJR Am J Roentgenol* 183:1637–1644, 2004. Reprinted with permission from the American Journal of Roentgenology.)

T1-weighted fat-suppressed images because of the presence of methemoglobin. Dynamic enhanced MDCT or T1-weighted gadolinium-enhanced MR images show a pseudoaneurysm as a rapidly enhancing mass similar in contrast density to the adjacent arteries and aorta. Spill of contrast material into the retroperitoneum due to active bleeding, as well as fresh blood in the peritoneal cavity, can also be diagnosed. It is important to have a high index of suspicion for pseudoaneurysm in

patients with history of pancreatitis and a suspected mass in the pancreas or its vicinity and not perform biopsy of these lesions without prior administration of contrast material or Doppler sonography to exclude a pseudoaneurysm (Fig. 97-25; see also Fig. 97-23). If the source of bleeding is obscured by the surrounding hemorrhage, angiography is crucial in identifying the presence and precise location of the bleeding pseudoaneurysm. Therapeutic arterial embolization of the bleeding

Figure 97-25 Pancreatic pseudoaneurysm. **A.** Axial nonenhanced MDCT image shows expansile lesion (arrow) in pancreatic body, surrounded by contrast material and air from previous ERCP. **B.** Axial arterial phase contrast-enhanced MDCT image clearly shows that the “mass” is a large pseudoaneurysm (arrow). In patients who present with suspected pseudocyst or pancreatic mass for drainage, the intravenous administration of contrast material is critical, as illustrated in this example. This pseudoaneurysm was subsequently embolized.

vessel is required; it is an emergency, lifesaving procedure. Massive hemorrhage from ruptured vessels or pseudoaneurysms requires surgical treatment.

Chronic Pancreatitis

Chronic pancreatitis is a relatively uncommon disease that has been increasing in frequency in the Western world. It is a disease of prolonged pancreatic inflammation characterized by irreversible morphologic and functional damage to the pancreas.¹⁵⁹⁻¹⁶¹

The clinical diagnosis of chronic pancreatitis can be difficult for treating physicians, especially in its early phases, as the findings are nonspecific and imaging features may not be definitive. The diagnosis by imaging relies on morphologic changes of the pancreas that may not be seen in early stages of the disease. The main features include parenchymal atrophy, chronic inflammatory changes, and fibrosis of the pancreas. The incidence of pancreatic cancer is significantly elevated in patients with chronic pancreatitis.^{161,162}

ETIOLOGY

In the United States, approximately 75% of cases of chronic pancreatitis are due to alcoholism. Continued consumption of alcohol for a 3- to 12-year period is necessary before the manifestations of chronic pancreatitis develop.¹⁶² In contrast to their major role in the development of acute pancreatitis, gallstones play little role in the etiology of chronic pancreatitis. Hyperlipidemia, hyperparathyroidism, trauma, and pancreas divisum have been implicated as risk factors for development of chronic pancreatitis.

CLINICAL FINDINGS

Pain is the predominant clinical finding in 95% of patients with chronic pancreatitis. The pain typically radiates from the epigastrium through the back and can be constant or intermittent and extremely difficult to palliate, frequently requiring narcotics or neurolysis. Weight loss often accompanies the pain, and these two findings raise the clinical suspicion of a malignant neoplasm. Endocrine and exocrine deficiencies occur with progressive destruction of the gland. Diabetes and malabsorption with steatorrhea eventually develop in approximately half the patients with chronic pancreatitis.^{162,163}

The clinical diagnosis of chronic pancreatitis, especially in its early stages, is often difficult. Histopathologic diagnosis is rarely available because of the risks associated with pancreatic biopsy, including acute pancreatitis, fistula, and hemorrhage.¹⁶⁴ Therefore, the diagnosis is based on clinical, morphologic, and functional abnormalities. ERCP and pancreatic function tests are considered the “gold standard” diagnostic procedures, but they have limitations, and prolonged clinical follow-up is sometimes required to confirm the diagnosis.

RADIOLOGIC FINDINGS

Plain Films

Typical pancreatic calcifications are diagnostic of chronic pancreatitis. They develop in 40% to 60% of patients with alcoholic pancreatitis, and approximately 90% of calcific pancreatitis is caused by alcoholism. Unfortunately, calcifications occur late in the course of chronic pancreatitis, being associated with severe disease. Most pancreatic calculi are small, irregular calcifications that may be diffuse (Fig. 97-26) or confined to a specific region of the pancreas. Although they can appear on plain films, CT is the most specific and accurate imaging modality to depict pancreatic calcifications.

Ultrasonography

The development of high-resolution linear array scanners has significantly increased the diagnostic accuracy of sonography in patients with pancreatitis. Whereas there have been significant improvements in ultrasound machines and high-frequency and high-resolution transducers, there have not been any recent studies to assess the utility of ultrasound in the diagnosis of chronic pancreatitis. Similar to CT, however, transabdominal sonography is insensitive for the diagnosis of early chronic pancreatitis.

Sonographic findings include abnormalities in gland size, irregular margins, inhomogeneous or heterogeneous echogenicity of parenchyma, and dilation of the pancreatic duct. The classic finding of chronic pancreatitis with sonography is calcifications seen as echogenic foci within the parenchyma or the main pancreatic duct. The calcifications may or may not shadow, depending on their size, and may show color Doppler twinkling artifact.¹⁶⁵ Pseudocysts are often present in chronic pancreatitis, and they are usually unilocular, anechoic, and

Figure 97-26 Pancreatic calcifications on plain abdominal radiographs. A. The entire gland contains numerous small calcifications located in the main pancreatic duct and its radicles (arrows). **B.** Pancreatic calcifications are located in the head and tail of the pancreas (solid arrows). The lack of calcifications in the body of the pancreas (open arrow) was due to displacement by a pancreatic pseudocyst.

sharply defined.¹⁶⁶⁻¹⁶⁸ Other complications of chronic pancreatitis, such as biliary dilation and splenic vein thrombosis, can also be detected with sonography.

Abnormalities in size and contour of the pancreas are the least sensitive indicators of chronic pancreatitis on ultrasound studies and may be subjective. Diffuse enlargement is often present early in the course of the disease, and atrophy or focal enlargement may be present later. An atrophic gland is usually difficult to appreciate, and some gland atrophy normally occurs with aging.¹⁶⁹

Pancreatic parenchymal echogenicity is also unreliable in the diagnosis of chronic pancreatitis because it can be normal, increased, or decreased. Decreased echogenicity occurs when there are acute exacerbations with parenchymal edema.^{164,169,170}

Dilation of the pancreatic duct is one of the most common sonographic abnormalities of chronic pancreatitis. It is seen in up to 90% of cases as a tubular, anechoic structure in the pancreatic body.

Endoscopic Ultrasound

EUS overcomes many of the limitations of transabdominal sonography because of the proximity of the transducer to the pancreas and the superior image resolution provided by high-frequency transducers. Although EUS is an invasive imaging modality, it has a low risk of complications. In many cases, EUS is helpful to elucidate the cause of pancreatitis, being able to detect small pancreatic tumors and microlithiasis not seen by other imaging modalities.¹⁷¹⁻¹⁷³ EUS can demonstrate biliary sludge and tiny stones that are often masked by the contrast medium on ERCP. In 77% to 92% of cases of idiopathic pancreatitis, EUS is able to diagnose the cause, which is small gallstones in the majority of these patients.^{173,174}

EUS findings indicative of chronic pancreatitis include parenchymal calcifications, hyperechoic foci or strands, pseudocysts, heterogeneous echotexture, and lobular contour of the gland.¹⁷⁵⁻¹⁷⁸ Ductal abnormalities include dilation and irregularity, hyperechoic walls, intraductal stones, and visible branches.^{176,178} Chronic pancreatitis is likely when more than two of these findings are present. With more than six findings, the disease is probably moderate to severe.¹⁷⁸ Unlike ERCP, EUS has the advantage of being able to evaluate simultaneously the pancreatic ductal system and the parenchyma. However, the diagnosis of chronic pancreatitis based on EUS changes alone

is controversial.^{164,175} There is usually a good correlation of EUS with ERCP in patients with moderate or severe chronic pancreatitis, but not in those with mild disease.^{176,179-181} Other studies reported abnormal findings on EUS examinations in patients with normal ERCP findings and pancreatic function test results, suggesting that EUS may overdiagnose chronic pancreatitis, or alternatively, it may be more sensitive than ERCP and function tests to detect subtle pancreatic changes.^{176,182} In a study of patients with suspected chronic pancreatitis, the addition of fine-needle aspiration improved the negative predictive value but did not improve the specificity of EUS findings in patients with normal ERCP findings.¹⁸³ EUS can be especially helpful when it is combined with fine-needle aspiration of a suspicious mass in patients with chronic pancreatitis. Biopsy of regional lymph nodes and assessment of tumor extension and vascular involvement can be performed with EUS to enhance staging in these patients. EUS also has therapeutic applications in chronic pancreatitis, such as to perform celiac plexus blocks to alleviate pain in patients without ductal obstruction and to guide internal stent placement for decompression of pseudocysts.^{184,185} Disadvantages of EUS include its cost, limited availability, long learning curve, and operator dependence.

Endoscopic Retrograde Cholangiopancreatography

Many of the reported findings of chronic pancreatitis are based on ERCP, and because of its relative invasiveness, it is not often used for diagnostic purposes but is used for therapeutic purposes. Less invasive studies, such as CT, MRI, and EUS, are now used mainly for diagnosis of chronic pancreatitis and its complications.^{186,187} In early chronic pancreatitis, the pancreatic duct is often normal, limiting the sensitivity of ERCP. The earliest changes involve the first-order and second-order side branches of the main pancreatic duct and include dilation and contour irregularity, clubbing, stenosis of the side branches, and opacification of small cavities. Some of these changes, however, can be seen in elderly normal patients and must be interpreted with caution in this age group.^{188,189}

With disease progression, the involvement of the main pancreatic duct increases with more dilation, mural irregularities, loss of normal tapering, and areas of stenosis or occlusion. If a solitary stricture is seen in the main pancreatic duct, the differential considerations include neoplasm and pseudocyst. Stenoses are usually shorter, smoother, and more symmetric in

pancreatitis than those associated with neoplasm.^{190,191} Biopsy of suspicious lesions or brushing and collection of pancreatic secretions can be performed with ERCP and may be helpful to diagnose pancreatic carcinoma. In advanced chronic pancreatitis, the dilation is more marked, and intraductal calculi can be seen. The pancreatic duct and side branches may have a “chain of lakes” appearance.

According to the Cambridge classification, chronic pancreatitis is considered mild if the main pancreatic duct is normal but at least three side branches are abnormal. Moderate disease requires abnormalities in the main pancreatic duct and in more than three side branches. Severe disease includes the abnormalities of moderate disease plus one of the following: a large cavity, ductal obstruction, filling defects, severe dilation, or irregularity.¹⁹²

ERCP is able to detect early chronic pancreatitis before morphologic abnormalities can be seen on CT.¹⁶⁴ There is a good correlation between ERCP and histology in chronic pancreatitis. The correlation between pancreatic function tests and ERCP is limited, however, especially in the early stages of chronic pancreatitis.^{164,192,193} ERCP is also helpful in the treatment of complications of pancreatitis, such as pancreatic duct strictures and pseudocysts, avoiding the complications of surgery.¹⁸⁷

Magnetic Resonance Cholangiopancreatography

ERCP used to be the standard imaging modality to evaluate the pancreaticobiliary tract, being a diagnostic and therapeutic procedure. Because of its invasiveness and potentially serious complications, however, ERCP is ideally reserved for patients who need therapeutic intervention. MRCP has been increasingly used in patients with suspected pancreatitis or pancreaticobiliary abnormalities because it lacks ionizing radiation, does not require iodinated contrast material, and is noninvasive, sparing the patient from potential complications. MRCP is also helpful in patients with anatomic abnormalities that impede cannulation of the common bile duct or pancreatic duct. With heavily T2-weighted sequences, MRCP is able to depict fluid-filled structures, such as pseudocysts, and to detect abnormalities of the pancreatic duct, including dilation, irregularity, intraductal stones, and multiple or severe obstructions, which may be a limitation for ERCP.^{194,195} MRCP has the advantage of showing the ductal segments proximal and distal to an obstruction, being able to evaluate its character, extent, location, and cause.

ERCP and more recently MRCP are helpful to evaluate the pancreatic duct for findings of chronic pancreatitis in patients with abdominal pain that is refractory to medical therapy.¹⁹⁵⁻¹⁹⁷ The sensitivity of MRCP to detect ductal abnormalities and dilation ranges from 56% to 100%, and the specificity ranges from 86% to 100%.¹⁹⁵⁻¹⁹⁷ Stricture or obstruction of the pancreatic or bile duct by stones is a major cause of pain and one of the main indications for surgery in chronic pancreatitis.¹⁹⁸ In the presence of ductal dilation, ductal drainage procedures combined with partial resection of the head of the pancreas may result in long-term pain relief in 60% to 80% of patients.

The administration of secretin during MRCP allows evaluation of the exocrine function of the pancreas, improves delineation of the pancreatic duct, and may be useful to detect abnormalities of the side branches in early chronic pancreatitis before morphologic changes seen on imaging.^{72,199,200} Secretin temporarily distends the pancreatic ducts by inducing pancreatic secretions and increasing the tone of the sphincter of Oddi.

Secretin also improves detection of ductal narrowing and endoluminal filling defects in severe chronic pancreatitis.²⁰⁰ Significant correlation between reduced duodenal filling scores during secretin-enhanced MRCP and impaired pancreatic exocrine function has been reported, and it can be performed with semi-quantitative or quantitative measurements.^{199,201-205} Normal quantitative exocrine function consists of complete filling of the duodenum with pancreatic fluid output. Suboptimal quantitative exocrine function consists of filling of only a portion of the duodenum. Diffusion-weighted imaging after secretin may be helpful.^{202,203,206}

Computed Tomography and Magnetic Resonance Imaging

CT imaging is considered by many to currently be the best initial imaging test for the diagnosis of chronic pancreatitis.^{164,207-209} It is widely available and reproducible and allows comprehensive evaluation of the pancreas and adjacent organs to help make the diagnosis of chronic pancreatitis and to exclude other causes of symptoms, such as abdominal pain or weight loss. The diagnostic criteria for chronic pancreatitis on CT and MR examinations are based on assessment of the size and contour of the gland, dilation and shape of the pancreatic duct, and presence of ductal calcifications^{164,190,210} (Fig. 97-27). CT has reported sensitivities of 50% to 90% and specificities of 55% to 85% in the detection of chronic pancreatitis.²⁰⁹ Despite marked improvements in CT technology since this initial study in 1989 by the Mayo Clinic, there have not been any recent studies to evaluate the accuracy of CT in the diagnosis of chronic pancreatitis.

Although CT correctly detects the morphologic alterations of chronic pancreatitis, its ability to evaluate severity of disease is more limited. These shortcomings are related to (1) the inability of CT to accurately diagnose incipient forms of chronic pancreatitis that do not exhibit gross morphologic changes and (2) poor correlation between functional exocrine and endocrine deficit and pancreatic morphology on imaging studies. Compared with ERCP and pancreatic function tests, CT is not sensitive in the diagnosis of early chronic pancreatitis. Some experts^{105,211-213} believe that MRI can detect findings of

Figure 97-27 Chronic pancreatitis. Axial contrast-enhanced MDCT image shows pancreatic atrophy with diffuse calcifications, mild dilation of the pancreatic duct, and a 1.2 × 1-cm pseudocyst (arrow) in the pancreatic body.

Figure 97-28 Chronic pancreatitis. **A.** Axial contrast-enhanced MDCT image shows pancreatic atrophy with multiple diffuse calcifications in a patient with chronic pancreatitis due to alcohol abuse. **B.** Axial T1-weighted fat-suppressed spoiled gradient-echo MR image shows decreased heterogeneous signal intensity of the pancreas and irregular dilation of the main pancreatic duct (arrows). **C** and **D.** Axial gadolinium-enhanced T1-weighted fat-suppressed spoiled gradient-echo MR images show decreased pancreatic enhancement during the arterial phase (**C**) and delayed enhancement in the venous phase (**D**) related to fibrosis due to chronic pancreatitis. Dilated pancreatic duct (arrows in **C**) is more clearly visualized after gadolinium enhancement. (**B-D** from Miller FH, Kepcke AL, Wadhwa A, et al: MRI of pancreatitis and its complications: Part 2, chronic pancreatitis. *AJR Am J Roentgenol* 183:1645–1652, 2004. Reprinted with permission from the American Journal of Roentgenology.)

chronic pancreatitis before CT on the basis of signal intensity abnormalities of the pancreas, which may be seen before abnormalities involving the pancreatic duct. These changes are best visualized on unenhanced and gadolinium-enhanced T1-weighted fat-suppressed images. The normal pancreas is high signal intensity due to the presence of acinar proteins and enhances markedly after the administration of gadolinium. Chronic pancreatitis and associated fibrosis result in loss of proteinaceous material and decreased signal intensity of the pancreas. Unlike the normal pancreas, the chronically inflamed and fibrotic pancreas shows decreased and heterogeneous enhancement during the arterial phase after administration of contrast material and relatively increased enhancement on later phases.^{105,211,212,214} (Fig. 97-28). Zhang and coworkers²¹³ found a sensitivity of 92% and specificity of 75% for the diagnosis of chronic pancreatitis based on abnormal enhancement pattern, as opposed to 50% diagnostic sensitivity based on morphologic changes of the pancreas.

Alteration in the size of the pancreas with atrophy is often seen in chronic pancreatitis; however, the gland may be normal or only slightly increased in size in 15% to 20% of cases, making the diagnosis more difficult. In one series, focal enlargement was present in 30% and atrophy of the gland in 54% of patients²⁰⁹ (see Fig. 97-27). Significant atrophy of the pancreas may be seen in elderly persons without chronic pancreatitis. Evaluation of the history and clinical and functional findings may be necessary for differential diagnosis. Focal enlargement of the gland produced by a chronic inflammatory mass may simulate a pancreatic neoplasm. In these cases, when CT is inconclusive, MRI may provide additional diagnostic

information; however, regardless of the imaging modality used, this distinction can be difficult.^{215,216} Several studies have demonstrated that focal pancreatitis and pancreatic carcinoma may have similar appearance and pattern of enhancement on CT and MRI because of the presence of fibrosis in both types of lesions.^{212,217-219} As a result, both pancreatic carcinoma and focal chronic pancreatitis may have restricted diffusion from fibrosis with lower apparent diffusion coefficient values. Both conditions may also cause dilation of the pancreatic duct and common bile duct (double duct sign), ductal strictures, and arterial encasement and peripancreatic venous obstruction.²¹⁶ In addition, carcinoma develops in 2% to 3% of cases of chronic pancreatitis, and this malignant degeneration is often difficult to appreciate on CT.²²⁰ A new or rapidly increasing homogeneous and ill-defined pancreatic mass, which can be detected by comparison with previous CT examinations or short-term follow-up, is indicative of malignant disease. Imaging features that favor the diagnosis of inflammatory mass related to chronic pancreatitis over adenocarcinoma include a nondilated or smooth tapering pancreatic duct coursing through the mass (duct penetrating sign), presence of pancreatic calcifications, lower ratio of duct caliber to pancreatic gland width, and irregular ductal dilation.^{212,217,219} The imaging features of adenocarcinoma and focal pancreatitis often overlap, however, and complementary studies including ERCP and EUS with fine-needle aspiration biopsy may be required for definite diagnosis.

Dilation of the pancreatic duct and its secondary radicles (>2 to 3 mm in size) is characteristic of chronic pancreatitis (Figs. 97-29 and 97-30). In advanced disease, the main duct appears

beaded, irregular, or smooth, often containing stones (Fig. 97-31). These pancreatic duct abnormalities are better demonstrated on MRI and MRCP examinations compared with CT scans. Subtle changes in side branches seen in early chronic pancreatitis, however, are best depicted on ERCP. The use of three-dimensional thin-slice MRCP images has improved delineation of the pancreatic duct, and if warranted, secretin can be used to improve pancreatic duct distention. The pancreatic duct should be visualized entirely to the level of the papilla because small tumors of the head of the pancreas may produce similar findings. The pancreatic duct may be dilated in patients with senile atrophy of the pancreas, mimicking chronic pancreatitis.

Pancreatic calcifications (see Figs. 97-27 and 97-28) are seen on CT scans in approximately 50% of patients with chronic pancreatitis.^{209,210} These calcifications are the most reliable imaging indicator of the disease. They can be scattered throughout the gland, isolated, or focal in the head or body of the pancreas. Calcifications vary from innumerable to single and small. The CT findings of chronic calcific pancreatitis are more difficult to visualize on MRI as it is less able to demonstrate calcifications compared with CT. MRI, however, may be helpful

in demonstrating the intraductal nature of stones as T2-weighted images easily show the low signal intensity stone in contrast to the high signal intensity pancreatic fluid in the duct.^{96,214}

Pseudocysts of various sizes may be present within the pancreas or in an extrapancreatic location. They occur in 25% to 60% of patients with chronic pancreatitis and are usually stable.^{13,30}

Pseudoaneurysms and thrombosis of the splenic vein with extensive collateral circulation and gastric varices are sometimes encountered in chronic pancreatitis and can be readily diagnosed by CT and MRI (Fig. 97-32). In addition, patients with repeated episodes of acute exacerbation may present with an acute abdominal catastrophe, dropping hematocrit, and evidence of massive intra-abdominal bleeding.

Pancreaticopleural Fistula

Pancreaticopleural fistula can occur in acute or chronic pancreatitis or as a result of pancreatic trauma. Pancreatic secretions from a ruptured pancreatic duct dissect through the aortic or esophageal hiatus or directly through the diaphragm and reach

Figure 97-29 Early chronic pancreatitis. Coronal T2-weighted thick-slab RARE MR image shows mild dilation of the secondary branches of the pancreatic duct (arrows) and pseudocyst (P) in the pancreatic tail. The main pancreatic duct (PD) and the common bile duct (CBD) have normal caliber. (From Miller FH, Keppke AL, Wadhwa A, et al: MRI of pancreatitis and its complications: Part 2, chronic pancreatitis. *AJR Am J Roentgenol* 183:1645–1652, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 97-31 Severe chronic pancreatitis. Axial T2-weighted HASTE MR image shows dilation of the main pancreatic duct and side branches, giving a "chain of lakes" appearance. The pancreas is atrophic and contains signal void areas (arrows) related to calcifications from chronic pancreatitis. (From Miller FH, Keppke AL, Wadhwa A, et al: MRI of pancreatitis and its complications: Part 2, chronic pancreatitis. *AJR Am J Roentgenol* 183:1645–1652, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 97-30 Chronic pancreatitis. A. Axial contrast-enhanced MDCT image shows diffuse calcifications in the pancreas with a dilated main pancreatic duct (arrows) measuring 9 mm and dilated side branches. **B.** Coronal T2-weighted MR image shows the dilated pancreatic duct and secondary radicles (arrows) associated with chronic pancreatitis. (B from Miller FH, Keppke AL, Wadhwa A, et al: MRI of pancreatitis and its complications: Part 2, chronic pancreatitis. *AJR Am J Roentgenol* 183:1645–1652, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 97-32 Splenic vein thrombosis. **A.** Axial enhanced T1-weighted fat-suppressed spoiled gradient-echo MR image shows low signal intensity thrombus (arrows) in the splenic vein. **B.** Axial contrast-enhanced MDCT image from another patient shows pancreatic pseudocyst (P) and the presence of collateral vessels (arrows), suggesting splenic vein occlusion. (A from Miller FH, Keppke AL, Dalal K, et al: MRI of pancreatitis and its complications: Part 1, acute pancreatitis. *AJR Am J Roentgenol* 183:1637–1644, 2004. Reprinted with permission from the American Journal of Roentgenology.)

Figure 97-33 Pancreaticopleural fistula. **A.** Axial contrast-enhanced MDCT image shows fluid extending through the diaphragm (arrows) from the abdomen into the pleural space in a patient with recurrent pleural effusions. **B.** Coronal contrast-enhanced MDCT image shows the fluid (black arrow) extending superiorly from the disrupted pancreatic duct into the chest, creating a left pleural effusion (white arrow). Without the coronal reformatted image, it is more difficult to make this diagnosis. **C.** ERCP confirms the CT findings, showing a fistula (arrow) from the pancreatic duct with the fluid extending into the chest.

the mediastinum, pleural cavities, pericardium, or bronchial tree. Patients usually present with large pleural effusions and dyspnea. A high index of suspicion for pancreaticopleural fistula is required. CT and MRI may show the fistula, especially when coronal images are used, as well as the changes of chronic pancreatitis, which are usually present (Fig. 97-33). ERCP has been considered the best imaging modality for evaluation of pancreaticopleural fistulas, but technical failures may result from incomplete opacification of the pancreatic duct or a long fistulous track. MRCP may depict the fistula and the ductal anatomy and can be helpful in the surgical planning of these patients, potentially replacing ERCP.²²¹

Groove Pancreatitis

Patients who suffer repeated episodes of pancreatitis or acute exacerbations of chronic pancreatitis may develop a form of segmental pancreatitis described as groove pancreatitis, in which the inflammatory reaction and fluid collection dissect into the “groove” between the duodenum, the head of the pancreas, and the common bile duct (Fig. 97-34).

Groove pancreatitis has been most frequently reported in young men with a history of alcohol abuse. There is no clear evidence for its exact pathogenesis. Multiple factors have been suggested to play a role in its development. Pancreatic heterotopia, abnormal development of the Santorini duct, pancreas

Figure 97-34 Groove pancreatitis. **A.** Axial contrast-enhanced MDCT shows hypoenhancing inflammatory tissue containing low-density cyst (arrow) in the groove between the duodenum (D) and the pancreatic head (P). **B.** Axial T1-weighted fat-suppressed spoiled gradient-echo MR image shows low signal intensity of the inflammatory mass (arrow) between the high signal intensity pancreatic head (P) and the duodenum. **C** and **D.** The mass (arrow) has decreased enhancement in the arterial phase (**C**) and delayed enhancement in the venous phase (**D**) after gadolinium administration because of fibrosis. (**A-D** from Miller FH, Keppke AL, Wadhwa A, et al: MRI of pancreatitis and its complications: Part 2, chronic pancreatitis. *AJR Am J Roentgenol* 183:1645–1652, 2004. Reprinted with permission from the American Journal of Roentgenology.)

divisum, peptic ulcer disease, and alcohol abuse are precipitating risk factors.²²²

Two forms of groove pancreatitis have been described, the pure form and the segmental form. The pure form is associated with scar tissue in the groove without pancreatic involvement; the segmental form includes scar tissue in the groove and involvement of the pancreatic head. Because of the enzymatic action of pancreatic secretions, as many as 50% of patients develop duodenal stenosis or strictures of the common bile duct.¹¹¹ The recognition of groove pancreatitis is important to distinguish it from pancreatic and duodenal carcinoma, which can be challenging.²²³⁻²²⁵ With groove pancreatitis, contrast-enhanced CT shows a poorly enhancing lesion extending between the duodenum and the pancreatic head. Cysts in the groove or duodenal wall and duodenal stenosis are often seen. The head of the pancreas enhances normally. MR findings of groove pancreatitis include a sheetlike fibrotic mass between the pancreatic head and a thickened duodenal wall associated with cystic changes in the duodenal wall.²²⁶ This fibrotic mass is hypointense to the pancreas on T1-weighted images and can be hypointense, isointense, or slightly hyperintense on T2-weighted images. The cystic component is low signal intensity on T1-weighted images and high signal intensity on T2-weighted images and does not enhance because of its fluid content. The fibrotic component demonstrates delayed enhancement after the administration of gadolinium and is easily demarcated from the normal pancreas, which has marked enhancement initially and less intense enhancement on more delayed images (see Fig. 97-34).^{212,227} Similar duodenal changes, referred to as cystic

dystrophy of the duodenal wall, have been reported in patients with acute pancreatitis and heterotopic pancreatic tissue in the duodenum.²²⁸ The cystic lesions in the duodenal wall may compress the common bile duct and main pancreatic duct, causing duct dilation.

MRCP is the imaging modality of choice for evaluation of the biliary and pancreatic ducts in groove pancreatitis.²²³ The main pancreatic duct usually appears normal in the pure form of groove pancreatitis but may have mild dilation in the segmental form, which presents with a focal hypodense lesion in the head of the pancreas and duodenal wall.²²³ In general, groove pancreatitis causes a smooth, long, and medially deviated common duct with stenosis in the distal common bile duct or intrapancreatic portion of the common bile duct.

The distinction of groove pancreatitis from cancer may be difficult (Fig. 97-35). Marked dilation of the main pancreatic duct, encasement and invasion of the peripancreatic vessels and tissues, and associated liver lesions favor malignant adenocarcinoma. In contrast, the characteristic location of a mass near the groove, cysts in the duodenal wall, and lack of encased and invaded peripancreatic vessels are more suggestive of segmental groove pancreatitis. Peripancreatic lymph nodes may also be seen, making the diagnosis difficult to distinguish from malignant disease. The findings may be nonspecific, and the discrimination between an inflammatory pancreatic mass and a malignant neoplasm can be very difficult and require biopsy, especially if the clinical features do not suggest groove pancreatitis.

Figure 97-35 Pancreatic adenocarcinoma mimicking groove pancreatitis. Axial (A) and coronal (B) contrast-enhanced MDCT shows hypoenhancing mass (arrow) between the duodenum and pancreatic head from pancreatic cancer.

Figure 97-36 Autoimmune pancreatitis. A. Axial contrast-enhanced MDCT shows uniformly enlarged pancreas. Note peripancreatic hypodense rim suggestive but not diagnostic of autoimmune pancreatitis. B. Axial T1-weighted image shows decreased enhancement of the pancreas with hypointense rim. C. T2-weighted image shows sausage-shaped appearance of pancreas. D. Axial contrast-enhanced T1-weighted image after therapy shows atrophy of the pancreas.

Autoimmune Chronic Pancreatitis

Autoimmune chronic pancreatitis (AIP) has unique clinical, histologic, and imaging features.²²⁹ It has an autoimmune mechanism and has been seen as an immunoglobulin G subtype 4 (IgG4) systemic disease; it can affect multiple organs, including the pancreas, bile ducts, kidney, retroperitoneum, lungs, salivary glands, and lymph nodes.^{229,230} It may coexist with diabetes mellitus and autoimmune diseases, such as Sjögren's syndrome, primary sclerosing cholangitis, and primary biliary cirrhosis. AIP may be relatively asymptomatic or be manifested as painless jaundice from an obstructive pancreatic mass. It occurs predominantly in middle-aged or older men and usually shows a remarkable response to steroids.^{231,232} Most of the patients are older than 50 years, and overall prevalence of AIP has been reported to be around 5% to 6% of patients suffering

from chronic pancreatitis.²³¹ Laboratory findings may include increased levels of serum IgG4. Pancreatic fibrosis with infiltration of lymphocytes and plasma cells, characteristically around the periductal area of pancreatic tissue, is seen on histopathologic examination.²³²

Imaging studies show a rare association of diffuse enlargement of the pancreas with irregular narrowing of the pancreatic duct.²³¹ Diffuse hypoechogenicity of the pancreas is seen on transabdominal sonography, which is nonspecific for the diagnosis. On CT and MRI, the pancreas appears diffusely enlarged, with a sausage-like appearance, usually without calcifications or stones.^{231,233,234} Typical findings of AIP on cross-sectional imaging include diffuse enlargement of the pancreas with loss of lobulation of the pancreatic border, narrowing of the main pancreatic duct, and capsule-like rim (Fig. 97-36).^{233,235} On MRI, the involved pancreas is hypointense on T1-weighted

Figure 97-37 Autoimmune pancreatitis. **A.** Axial contrast-enhanced MDCT image shows a uniformly enlarged pancreas, with sharp outline. Note peripancreatic hypodense rim (arrows), which is suggestive of autoimmune pancreatitis but not diagnostic. **B.** ERCP shows segmental irregular narrowing (black arrows) of the pancreatic duct at the level of the body of the pancreas. The ductal segments adjacent to the stricture are minimally dilated. Stricture of the distal common bile duct is also seen (white arrow). **C.** ERCP shows multiple strictures (arrows) in the intrahepatic ducts.

imaging and hyperintense on T2-weighted imaging and shows restricted diffusion.^{233,236,237} As in chronic pancreatitis of other causes, the pancreas shows decreased enhancement in the arterial phase and increased enhancement in delayed phases after administration of contrast material. A characteristic low-density rim, likely composed of fibrous tissue and inflammatory reactions, is often seen surrounding the pancreas.^{227,231} This capsule-like rim shows delayed enhancement on dynamic imaging and low signal intensity on T1- and T2-weighted MR images.²²⁷ Diffuse or segmental irregular narrowing of the main pancreatic duct associated with strictures of the intrahepatic and extrahepatic biliary tract is typically demonstrated on ERCP (Fig. 97-37). Diffuse narrowing of the main pancreatic duct without significant upstream dilation supports the diagnosis, unlike the typical more severe dilation seen with cancer or chronic pancreatitis. Biliary thickening and enhancement or mass and lymphadenopathy may also be seen, mimicking sclerosing cholangitis or cholangiocarcinoma. Gallbladder wall thickening may also be present.²³⁵ MRCP shows the biliary tract abnormalities well but does not show the stenosis of the pancreatic duct as well as ERCP does.^{227,238} Other features of chronic pancreatitis, such as pseudocysts and pancreatic calcifications, are rare with AIP. Segmental involvement can mimic malignant disease. Unlike pancreatic adenocarcinoma, AIP can be distinguished by the lack of vascular invasion or findings to suggest metastases.

AIP has many extrapancreatic manifestations, including most commonly involvement of the biliary tree (up to 80%).^{230,239} Renal (35%) and retroperitoneal (10%) involvement

is common. In the majority of patients, renal involvement is manifested as bilateral multiple round or wedge-shaped renal cortical lesions, but it can also infiltrate kidneys diffusely or show a single masslike lesion arising from the renal parenchyma. Retroperitoneal fibrosis, a soft tissue mass surrounding the aorta and inferior vena cava, is seen in 10% to 20% of patients. Salivary and lacrimal gland enlargement may be seen in 14% to 24% of patients. Gastrointestinal tract abnormalities and pulmonary opacities or lesions have been reported in AIP. These extrapancreatic manifestations should be considered additional clues that can be helpful in diagnosis of AIP, particularly in atypical manifestations of AIP, such as segmental or masslike pancreatic lesions or atrophy of the pancreas due to late stages of AIP.²³⁰

The diagnosis of AIP is highly suspected when these typical imaging features are combined with supportive serology findings. There has been development of several different criteria for the diagnosis, including the Mayo Clinic histology, imaging, serology, other organ involvement, and response to therapy (HISORT) criteria and the Japan Pancreas Society and Asian diagnostic criteria.²⁴⁰⁻²⁴² EUS is most helpful for fine-needle aspiration or biopsy, especially when the diagnosis is not clear and cancer needs to be excluded.^{243,244}

Corticosteroid therapy has been used for diagnostic and therapeutic purposes by gastroenterologists experienced in treating AIP after pancreatic cancer has been excluded, although disease recurrence can be seen in up to 40% of patients.²⁴⁵ After corticosteroid therapy, the pancreatic morphologic abnormalities of the common bile duct and pancreatic

duct usually resolve.²⁴⁶ The two most important expected findings after corticosteroid therapy for AIP are significant decrease in pancreatic size and normalization of the main pancreatic duct appearance. Improvement of biliary tree involvement and other extrahepatic manifestations is also frequently reported. Whereas the diffuse form of AIP may be considered difficult to discriminate from mild acute pancreatitis, significant response to steroid therapy and lack of retroperitoneal fluid and inflammation in AIP can help distinguish these two entities.²⁴⁶

It has been shown that AIP responds well to corticosteroid therapy when some features exist on imaging. This may reflect the presence of various stages of disease evolution from early active inflammation to late sclerosis and fibrosis stages. Diffuse enlargement of the pancreas, the presence of a peripancreatic halo, ductal obliteration, or wall thickening usually responds rapidly to corticosteroid therapy and may relate to active inflammation. In some patients, features of pancreatic tail retraction, persistent ductal stenosis, and focal masslike inflammatory lesions have been reported to be the imaging findings that are suggestive of a reduced or suboptimal response to steroid therapy, probably because of the presence of late-phase fibrosis or sclerosis.²⁴⁶⁻²⁴⁹

Summary

Experience accumulated since the late 1970s has shown that CT is the single most important imaging modality in evaluating patients with pancreatitis. CT has high sensitivity and specificity in diagnosis of moderate and severe pancreatitis as well as in detection of serious complications that are often

clinically unsuspected. In addition, CT plays a valuable role as an early predictive indicator of disease severity. Patients with fluid collections and pancreatic necrosis are at high risk for development of complications. These patients should be closely monitored clinically and with follow-up CT examinations. They require intensive care treatment and percutaneous or surgical drainage procedures when sepsis develops. MRI has also become an accurate imaging modality for assessment of pancreatitis. It is especially helpful in patients with allergy to iodinated contrast agents or poor renal function and to evaluate the pancreaticobiliary tract, to characterize complex fluid collections, and to diagnose early chronic pancreatitis. Sonography is used mainly to exclude a diagnosis of gallstones and biliary obstruction. The role of ERCP has diminished as MRCP emerged as a noninvasive alternative diagnostic tool. ERCP is mainly used for interventional procedures, such as endoscopic therapy for complications of pancreatitis and ductal obstruction, and to perform tissue biopsy to differentiate benign from malignant clinical and imaging features. It is occasionally used to provide a road map of the pancreatic duct before surgical procedures and to diagnose early side branch abnormalities in chronic pancreatitis. Noninvasive imaging, however, has increased in use for the diagnosis, management, and treatment of patients with acute and chronic pancreatitis during the last few decades and has played a major role in these patients.

ACKNOWLEDGMENTS

We would like to thank Dr. Areza Ghasemi and Dr. Elise Saddleton with preparation of this manuscript. We also wish to thank Holly Harper and David Botos for their assistance.

Secondary Pancreatic Neoplasms

The World Health Organization classification of pancreatic neoplasms is remarkable for the wide variety and type. This is because benign, borderline, and malignant tumors can arise from exocrine, neuroendocrine, intraductal, and stromal elements. In addition, secondary (metastatic) neoplasms and non-neoplastic tumor-like conditions (e.g., mass-forming chronic pancreatitis) affect the pancreas. However, in clinical practice, only a few of these (adenocarcinoma, cystic neoplasms, pancreatic neuroendocrine tumors, and metastases) are encountered with any frequency. This chapter attempts to review the protocol details that are necessary to be used for patients thought to have a pancreatic neoplasm; the roles of additional imaging, such as positron emission tomography (PET) and endoscopic ultrasound (EUS); and the imaging appearances of these tumors.

Ductal Adenocarcinoma

Pancreatic ductal adenocarcinoma (PDA) is the fourth most common cause of cancer deaths for both men and women in the United States. The American Cancer Society estimates approximately 45,000 new cases with 38,000 deaths for 2014.¹ This is a striking increase from the 32,000 expected new cases of ductal cancers predicted in 2005; a true increase in incidence

is documented between 1998 and 2008.² Despite improvements in imaging, surgery, radiation, and chemotherapy and rapidly emerging molecular understanding, mortality remains high; 23% of patients will be alive at 1 year from diagnosis, whereas 4% will be alive at 5 years. Established risk factors for development of PDA include cigarette smoking, male African American, *BRCA2* gene positivity, hereditary pancreatitis, cirrhosis, diabetes mellitus, chronic pancreatitis, hypercholesterolemia, obesity, Peutz-Jeghers syndrome, Lynch syndrome, vitamin D deficiency, certain occupations, and carcinogens.³ Common symptoms include weight loss, jaundice, floating stool, pain, dyspepsia, nausea, and depression. New-onset type 2 diabetes in patients older than 50 years may trigger investigation for PDA.⁴

The American Joint Committee on Cancer has developed a TNM-based staging system for pancreatic adenocarcinoma⁵; however, because only 15% to 20% of patients are candidates for surgery at the time of diagnosis, the majority of patients will not be able to be formally assigned to a stage. For all patients who do not undergo surgery, clinical staging is solely based on imaging.⁶ The quality of imaging can directly affect the accuracy of staging; patients deemed to have unresectable tumor at non-pancreatic-directed imaging have been shown to actually be surgical candidates.⁷

Ductal adenocarcinoma accounts for 85% to 90% of all pancreatic tumors; 60% to 70% arise in the head, 5% to 10% in the body, and 10% to 15% in the tail of the gland.^{8,9} Up to 22% of tumors can affect multiple regions of the gland (diffuse).¹⁰ By the time the tumors are discovered, they usually measure 2 to 3 cm in diameter. Pancreatic adenocarcinoma has scant cellular elements and elicits an intense desmoplastic response within the stroma surrounding the tumor. The stromal reaction encases intrapancreatic blood vessels, explaining why 90% of these masses are hypodense compared with background pancreas. The upstream main pancreatic duct may be obstructed, and the surrounding parenchyma is atrophic. Tumors in the head of the pancreas will also eventually obstruct the common bile duct. The tumor rapidly grows through lymphatics, along peripancreatic vessels, and along nerves; it may also grow along tissue planes into the surrounding duodenum and posterior wall of the stomach. Lesions in the tail of the pancreas infiltrate into the splenic hilum and into the left renal hilum. Distant metastases are most frequently found in the liver and peritoneal cavity. These can be present even in cases in which the tumor does not appear locally advanced.¹¹

The major blood vessels involved by PDA are the superior mesenteric artery, celiac axis, and branches. More frequently, the tumor will involve the superior mesenteric, splenic, and portal veins. Once the major arterial branches are involved with tumor, most surgeons agree that they are unresectable. However, experienced surgeons can achieve a negative-margin resection if the degree of contact between the tumor and the vessel is minimal. Most lymph node disease in pancreatic cancer is

found in unenlarged lymph nodes¹²; lymphadenopathy is unusual. Most surgeons will operate on patients who have lymph node disease within the field of resection. Distant lymph node disease is a contraindication to resection.

GOALS OF IMAGING

A high-quality imaging study is the first part of the evaluation of *all* patients thought to have pancreatic cancer.⁴ In most cases, multidetector computed tomography (MDCT), magnetic resonance imaging (MRI), or EUS, with needle aspiration biopsy, will serve as that procedure.^{13,14} Other imaging modalities, such as transabdominal ultrasound, diagnostic endoscopic retrograde cholangiopancreatography (ERCP), ¹⁸F-fluorodeoxyglucose PET (FDG PET), and receptor (somatostatin)-specific nuclear medicine studies, are secondary procedures. Examinations such as upper gastrointestinal series, hypotonic duodenography, and selective catheter angiography no longer have any role in the diagnostic work-up.

The choice of imaging study must take into account safety, patient comfort, and affordability combined with a sufficient sensitivity, specificity, and accuracy. The protocol for the imaging test is designed to detect the presence of a pancreatic neoplasm and to determine whether an individual patient has truly resectable disease.¹⁵ Timing of the imaging acquisition must be optimized to maximize lesion-to-background pancreas contrast differences, to evaluate the integrity of major peripancreatic arteries and veins, and to detect extrapancreatic metastases (Fig. 98-1). There is a high level of agreement that

high-quality MDCT using a multiphase acquisition protocol is the procedure of choice for these patients.^{4,16,17}

MULTIDETECTOR COMPUTED TOMOGRAPHY PROTOCOLS

Image data from MDCT examination is collected by use of the narrowest detector configuration. From the data acquisition, two sets of image data are reconstructed. The first set is reconstructed at familiar CT slice widths (3 or 4 mm); these images are sent to a picture archiving and communications system (PACS) or film. The second set is reconstructed at the thinnest possible slice width as determined by the detector (e.g., 0.75-mm sections from a 0.6-mm detector configuration).¹⁸ These isotropic data sets are sent to a three-dimensional (3D) workstation, allowing multiplanar reformatting, 3D volume rendering, CT angiography, and CT cholangiopancreatography (CTCP).¹⁹⁻²³ Utility of 3D imaging is enhanced by the use of neutral (close to water density) oral contrast material.²⁴

Proper delivery of intravenous contrast material and timing of the acquisition are critical for successful pancreatic CT. A low-osmolality intravenous contrast agent with high iodine concentration (370 mg I/mL) at a dose of 1.5 mg I/kg provides optimal pancreatic parenchymal and hepatic enhancement.²⁵ The contrast agent should be administered by power injector at a minimum rate of 3 mL but preferably between 4 and 5 mL/s. All investigators use a dual acquisition protocol.²⁶⁻²⁸ The first image set is acquired during the pancreatic phase (approximately 40 to 50 seconds), and a second image set is acquired

Figure 98-1 Pancreatic adenocarcinoma.

A. Adenocarcinoma of the tail of the pancreas in a 57-year-old man. During the pancreatic phase, the mass in the tail of the pancreas (arrow) is easily recognized. **B.** Adenocarcinoma, tail of pancreas; same patient as in **A**. During the portal phase, the mass is almost isodense with the remainder of the pancreas (arrow). **C.** Adenocarcinoma of the head of the pancreas in a 64-year-old woman. There is a low-attenuation region in the head of the pancreas (arrow). **D.** Adenocarcinoma, head of pancreas and same patient as **C**. The mass is unrecognizable 20 seconds later during the portal phase. Both cases illustrate the critical importance of pancreatic phase imaging.

during the portal venous phase (70 to 80 seconds) (Fig. 98-1).²⁹ Some advocate a three-phase protocol that includes an unenhanced acquisition; in our practice, we incorporate an unenhanced acquisition only when pancreatic neuroendocrine tumor is suspected.

Dual-energy CT acquisitions have the advantage of allowing the radiologist to view images acquired at two different energies (kVp). Viewing the images acquired at the lower energy or by simulating the contrast that might have been acquired at a lower beam energy (monoenergetic imaging) enhances tissue contrast by maximizing photoelectric interactions. This results in an increase in the attenuation of background pancreas with resultant increase in lesion-to-background conspicuity.^{30,31}

MAGNETIC RESONANCE IMAGING PROTOCOLS

A comprehensive (“one-stop shopping”) MRI evaluation of the pancreas and biliary tree can be performed by use of multiple acquisitions at multiple pulse sequences. In our practice, a pancreas-dedicated MRI evaluation includes an axial fat-suppressed fast (turbo) T2 sequence; two-dimensional (2D) axial in-phase and opposed-phase noncontrast T1-weighted sequences; axial and coronal single-shot fast spin-echo (HASTE or spoiled GRASS) T2-weighted acquisition; and multiphasic

gadolinium-enhanced, 3D T1-weighted gradient recalled acquisition with frequency selected fat suppression (VIBE) sequences during the phase of pancreatic enhancement and the portal phase of hepatic enhancement.³²⁻³⁶ Current MRI scanners can obtain diffusion-weighted sequences; however, these have been shown not to be reliable for pancreatic adenocarcinoma.^{37,38}

Magnetic resonance cholangiopancreatography (MRCP) is also performed with a heavily weighted T2 acquisition either in 2D with thick slab or 3D respiratory-triggered acquisition. The 2D pancreaticobiliary duct evaluation can also be obtained from the HASTE acquisitions.

MULTIDETECTOR COMPUTED TOMOGRAPHY FINDINGS

PDA appears as a hypodense mass with poorly defined borders compared with the background parenchyma during the pancreatic phase.³⁹ With current MDCT technology, non-contour-deforming tumors will be frequently encountered, underscoring the critical importance of imaging the pancreas during the phase of maximal background pancreatic enhancement, in which the tumor-to-gland attenuation difference is greatest.⁴⁰ In 11% of cases, pancreatic adenocarcinoma may be isoattenuating (Fig. 98-2).⁴¹ Secondary findings include dilation of the

Figure 98-2 Pancreatic adenocarcinoma. **A.** Locally unresectable pancreatic adenocarcinoma in a 78-year-old woman. There is an infiltrating mass projecting medially from the uncinate process appearing to contact the superior mesenteric artery over a greater than 180-degree circumference (arrow). **B.** Locally unresectable pancreatic adenocarcinoma, same patient as in **A.** This volume rendered CT angiographic view more optimally displays the mass (asterisk) and clearly depicts the complete contact of the superior mesenteric artery (arrow). **C.** Locally resectable pancreatic adenocarcinoma in a 68-year-old man. There is a mass (asterisk) in the body of the pancreas that contacts but does not surround the splenic artery. Note the upstream atrophy and main pancreatic duct dilation in the body and tail of the pancreas (arrow). On the basis of local staging, the tumor would be classified as borderline resectable. **D.** Locally resectable pancreatic adenocarcinoma but distant metastasis. Same patient as in **C.** The hepatic metastasis is seen on the portal acquisition; on the pancreatic phase, there is only a vague region of low attenuation. This case illustrates the differing times of peak enhancement of the pancreas and liver. The presence of the hepatic metastasis makes this case unresectable despite the fact that the tumor is locally resectable.

upstream pancreatic duct and dilation of the common bile duct when the tumor is located within the pancreatic head. Use of curved multiplanar reformatting or 3D volume rendering can improve detection of ductal dilation.⁴²

CT findings of major arterial encasement include obliteration of the normal fat between the pancreatic margin and the adjacent vessel; more than 180-degree contact between the tumor and the vessel; and morphologic changes in the artery, including narrowing or encasement of the affected artery.^{43,44} With 3D volume rendering, images of the pancreatic arterial supply can be created that rival conventional catheter angiography, making recognition of the vascular changes straightforward⁴⁵ (Fig. 98-2). CT angiographic images have been shown to be more accurate for detection of arterial involvement from pancreatic adenocarcinoma than by looking at traditional axial slices alone⁴⁶ (Fig. 98-3).

With improving MDCT technology, there is increasing appreciation of local spread of PDA before it actually encases major vessels. Predictable pathways for perilymphatic and perineural tumor infiltration have been correlated with detailed anatomic dissections. High-quality thin-section imaging is needed to view these changes.^{47,48} When spread along these pathways is suspected, the surgeon should be alerted, and neoadjuvant therapy may be appropriate before attempt at resection.⁴⁹

Criteria for venous invasion include more than 180-degree contact with a soft tissue mass and the vein. When the superior

mesenteric vein is involved with tumor, it may display a “tear-drop” configuration⁵⁰ (Fig. 98-4). Although soft tissue contact with the venous system has a high predictive value for nonresectability,⁵¹ significant involvement of the vein may be found at surgery when the imaging study fails to reveal any direct contact with the vein.⁵² It is therefore critical to evaluate the presence and pattern of collateral venous channels surrounding the pancreatic head.^{53,54} In advanced cases, collateral venous channels are easily recognized. Common collateral channels include prominent short gastric varices, gastrohepatic ligament varices, and gastroepiploic to gastroduodenal trunk. It is important to look for the small posterior pancreaticoduodenal veins; when these collaterals are present, there is a high likelihood that the tumor has involved the superior mesenteric vein to a degree that would preclude the ability to obtain a negative tumor margin⁵⁴ (Fig. 98-4).

MAGNETIC RESONANCE IMAGING FINDINGS

The appearance of the pancreatic mass will depend on the acquisition sequence used (Fig. 98-5). As outlined in the preceding section, a multisequence approach is used for a comprehensive evaluation. Because the pancreatic mass elicits a dense desmoplastic stromal response, most masses will have a shorter relaxation time than the surrounding normal parenchyma and therefore appear as a “dark” region. Contrast-enhanced pancreatic phase T1-weighted sequences are most

Figure 98-3 Pancreatic adenocarcinoma.

Adenocarcinoma of the head of the pancreas in a 58-year-old man. **A.** A 4-cm mass in the head of the pancreas tethers the superior mesenteric vein (arrow) and contacts the gastroduodenal artery (arrowhead). The lesion is classified as borderline resectable. **B.** The mass contacts the hepatic artery (arrow). **C.** Curved multiplanar reconstruction display shows that degree of contact with the hepatic artery is not circumferential (arrow). The gastroduodenal artery involvement is confirmed (arrowhead).

Figure 98-4 Pancreatic adenocarcinoma. Unresectable adenocarcinoma of the head of the pancreas in a 54-year-old man. **A.** The tumor in the head of the pancreas (asterisk) contacts the superior mesenteric vein (arrow). There was no contact with arteries. **B.** Whereas the degree of contact is less than 180 degrees, the intestinal veins (asterisks) join at the confluence with the splenic vein. A venous graft could not be placed because the drainage of intestinal venous branches would be obstructed.

effective in delineating the mass. Fat suppression will increase the conspicuity of the mass by significantly decreasing the signal from intraperitoneal and retroperitoneal fat, thereby increasing the signal from the pancreas, heightening contrast between normal parenchyma, the mass, and the pancreatic duct. PDA is hypointense compared with background pancreatic parenchyma, similar to CT findings. Liver metastases are best seen against a densely enhanced liver as occurs in the portal venous phase. Metastases possess a more rapid relaxation time than the background liver on both T1- and T2-weighted sequences and therefore will appear relatively bright. Detection of liver metastases is improved when diffusion-weighted sequences are obtained in addition to contrast-enhanced acquisitions.⁵⁵

Because the gadolinium-enhanced imaging sequences are acquired as a 3D volume, the arterial and venous anatomy can be displayed as MR angiographic images with imaging features of vascular involvement and tumor extension similar to those displayed on MDCT. Familiar 3D techniques, such as maximum intensity projection and volume rendering, can be used to create displays of the pathologic process in any useful plane.

ENDOSCOPIC ULTRASOUND

The accuracy of EUS in the diagnosis of pancreatic and periampullary neoplasm is well established.⁵⁶ However, with rapid improvement in both MDCT and MRI, EUS use is predominantly complementary to cross-sectional techniques and for case-by-case problem solving.⁵⁷ EUS is an excellent guide for fine-needle aspiration biopsy, with positive results in 75% of cases.⁵⁸ It has been shown that there is a statistically significant lower chance for development of peritoneal carcinomatosis after EUS biopsy as opposed to percutaneous fine-needle aspiration biopsy.⁵⁹

ACCURACIES OF MULTIDETECTOR COMPUTED TOMOGRAPHY, MAGNETIC RESONANCE IMAGING, AND ENDOSCOPIC ULTRASOUND

There is relatively uniform consensus at the time of this writing that MDCT ranges in overall accuracy between 86% and

99%.^{21,40,60-67} The positive predictive value of CT for predicting resectability ranges between 45% and 79% because the criteria for diagnosis of vascular invasion favor specificity over sensitivity.⁶⁸ However, there has been overall improvement coincident with improving technology.⁶⁹ This trend has continued; high-quality MDCT restaged 81 of 88 patients considered unresectable to resectable, with 94% having R0 resections.⁷ Centers that see a high volume of pancreatic cancer patients will obtain a repeated pancreas-dedicated CT study if outside imaging is considered inadequate.⁷⁰

Reported accuracy for MDCT in detection of arterial involvement is reported as high as 99%, with a negative predictive value of 100%.⁷¹ Confirmation of venous involvement is best assessed on hepatic phase images, and the negative predictive value approaches 100%.⁴⁰ Detection of lymph node metastasis is limited. With use of a short-axis diameter of more than 10 mm as the criterion for nodal involvement, CT has a reported sensitivity of 14%, a specificity of 85%, a negative predictive value of 82%, and an overall accuracy of 73%.¹²

Reported accuracies for high-quality multiacquisition MRI range between 76% and 89%.⁷²⁻⁷⁴ A meta-analysis of eight studies found the pooled sensitivity, specificity, and positive and negative likelihood ratio to be identical for CT and MRI for diagnosis of vascular invasion.⁷⁵ Some centers find the improved contrast sensitivity of MRI over CT useful for planning radiation therapy (see Fig. 98-5).

The most frequent cause of understaging of pancreatic adenocarcinoma is the failure of the detection of small metastases in the liver and peritoneal cavity. Imaging is poor in the detection of these small lesions. Small peritoneal implants may be present without ascites or other more flagrant signs of peritoneal carcinomatosis, making them extremely difficult to detect. A combination of CT scanning supplemented by laparoscopic ultrasound immediately before surgery in those patients deemed to have resectable tumor is an imaging strategy that has accuracy as high as that of more expensive tests, with preservation of the highest levels of quality-adjusted life-years.⁷⁶ In most clinical practice, MDCT is the primary imaging modality, with MRI reserved for patients with allergy to contrast material. EUS is used in cases in which ductal obstruction is visualized *without* a mass visible on the cross-sectional study

Figure 98-5 Pancreatic adenocarcinoma. **A.** MRI evaluation of a 68-year-old woman. *Top row:* Fat-saturated T2 sequence (left) and long T2 slab MRCP (right) reveal segmental main pancreatic duct dilation. *Middle row:* High b value diffusion-weighted image (left) shows restriction with high signal in region of change in duct caliber (arrow). Corresponding apparent diffusion coefficient map shows decrease in region of interest (arrow). This combination is characteristic of neoplasm. *Bottom row:* Image from gadolinium-enhanced gradient recalled echo sequence (left) reveals focal low signal mass at point of caliber change in pancreatic duct (arrow). Contrast is increased by use of subtraction imaging (right). **B.** Adenocarcinoma, head of pancreas, in a 52-year-old man. An infiltrating mass (asterisk) in the head of the pancreas is seen on pancreatic phase MDCT. **C.** Adenocarcinoma, head of pancreas; same patient as in **B**. The mass (asterisk) is more clearly delineated on the gadolinium-enhanced gradient recalled echo T1-weighted sequence. Radiation therapists find MR useful for more precise definition of tumor margins, resulting in better targeting.

and is the best method for obtaining tissue to confirm malignant disease.⁷⁷

With reported successes of newer neoadjuvant treatment options and increasing skill in surgical removal of tumor, consistent detailed reporting that specifically addresses each of the components of the status of a given tumor around which appropriate therapeutic decisions are made is desirable. Such reports guarantee that the examination has been adequately performed and carefully reviewed. Furthermore, these reports can serve as a record by which institutional accuracy in image interpretation can be measured as well as provide a uniform database for larger interinstitutional trials. The Society of Abdominal Radiology and the American Pancreatic Association called together a panel of experts in imaging, gastroenterology, and surgery to create a template for reporting of imaging findings in patients with pancreatic adenocarcinoma. The results have been published in both the radiology⁷⁸ and gastroenterology literatures.⁷⁹

CHANGES IN THE PANCREATIC DUCT

The main pancreatic duct is routinely visualized on MRCP performed with most current MR systems in clinical use. Rapid T2-weighted sequences and respiratory-gated long T2 3D sequences can show the normal duct in almost all cases. The duct can be visualized on high-quality pancreatic phase MDCT⁴² and with moderate frequency during the portal phase.⁸⁰ Minimum intensity projections and curved multiplanar reformatting facilitate recognition of the duct.

When this finding is observed on an imaging study, patients should undergo an intensive work-up to exclude malignant disease as the cause^{81,82} (Fig. 98-6). In one series, 71 of 86 isolated duct strictures were due to a malignant disease.⁸³ Pancreatic adenocarcinoma⁸⁴ and neuroendocrine tumor⁸⁵ are the most common tumor causes. Differential diagnosis includes main duct intraductal papillary mucinous neoplasm. When the entire duct is dilated, chronic pancreatitis cannot be excluded.

Isolated duct strictures may predate the typical imaging appearance of PDA and can be thought of as a sign of “early” pancreatic cancer. Several studies have documented that retrospective review of prior imaging studies in patients presenting with PDA will reveal abnormalities in the pancreas in nearly half of patients, the most common being segmental dilation of the main pancreatic duct. This finding can predate the clinical appearance of pancreatic neoplasm by as long as 18 months.^{86,87} In our practice, when we detect segmental pancreatic duct obstruction, the patient will be referred for EUS and biopsy; the high sensitivity and specificity for diagnosis of the underlying neoplasm are validated in the literature.⁸⁸ Small cysts (>5 mm) associated with a dilated pancreatic duct appear to be a predictor of future development of PDA.⁸⁹

OTHER IMAGING MODALITIES

Several other imaging modalities are in current use for imaging of pancreatic adenocarcinoma, including transabdominal ultrasound, ERCP, and FDG PET. Several reports have shown promise of FDG PET scanning to detect pancreatic cancer⁹⁰⁻⁹²;

Figure 98-6 Pancreatic adenocarcinoma: importance of main pancreatic duct. **A.** This 84-year-old man, who was being observed for prostate cancer, developed a segmentally dilated main pancreatic duct (arrow). **B.** The finding is confirmed on MRCP. The patient underwent a distal pancreatectomy and is alive 3 years after these imaging studies. **C.** The dilated pancreatic duct in this 69-year-old woman was discovered incidentally during surveillance for known carcinoma of the cervix. **D.** No mass is seen at the transition point. No discrete pancreatic mass was recognized at the time of surgery, but a distal pancreatectomy was performed. Poorly differentiated adenocarcinoma was present.

however, with improved MDCT and MRI balanced against the cost, most believe that PET-CT is complementary and best used on a case-by-case basis.⁹³

Transabdominal ultrasound will often be used in jaundiced patients to rapidly identify a dilated biliary tree. Whereas a dilated intrahepatic biliary tree is easily demonstrated, the specific cause of extrahepatic bile duct dilation is frequently difficult to establish. The most frequent reason for this is bowel gas obscuring the region of the pancreatic head and common bile duct. In selected patients, however, careful transabdominal technique can demonstrate the echogenic mass obstructing either the pancreatic or common bile duct. Contrast-enhanced transabdominal ultrasound has become an established technique to detect pancreatic lesions and to measure organ perfusion.⁹⁴

ERCP is often used preoperatively to place a drainage stent within an obstructed common bile duct. Several studies have shown that this preoperative stent placement should not be performed before surgical resection as there is a clear increase in the complication rate.⁹⁵ Most leading pancreatic surgeons will request common bile duct stenting when surgery will be delayed more than 14 days after diagnostic evaluation. Expandable metallic endoscopically placed endobiliary stents should be reserved for those patients with unresectable disease needing palliation.

Cystic Neoplasms

Cystic pancreatic neoplasms are frequently encountered on imaging studies. Despite a large accumulating clinical and imaging experience with these lesions, their behavior in individual patients is difficult to predict. Therefore, when they are detected on an imaging study, there will be uncertainty about the diagnosis and varying recommendations for follow-up or treatment⁹⁶ despite the fact that there has been improving ability to correctly characterize individual lesions on imaging studies.^{97,98}

Cystic pancreatic neoplasms can be divided into four distinct categories: serous cystadenoma (SCA); mucinous cystic neoplasm; intraductal papillary mucinous neoplasm (IPMN); and “other”⁹⁹ (Fig. 98-7). This classification helps in focusing of the imaging search for diagnostic features that allow differentiation of benign from malignant lesions, paralleling the management that is distinct within each category.

SEROUS CYSTADENOMA

SCA accounts for approximately 1% to 2% of all exocrine pancreatic neoplasms. The World Health Organization classification of pancreatic tumors considers SCA a benign lesion.¹⁰⁰ At the time of diagnosis, 25% to 50% of patients will be

Figure 98-7 Pancreatic cystic neoplasms. Classic imaging findings in four different patients. *Top left:* Serous cystadenoma with radially arrayed dense septa. *Top right:* Mucinous cystic tumor in a 45-year-old woman. Note the scant septa and typical location in the pancreatic tail. *Bottom left:* Branch duct IPMN. The minimum intensity projection CT shows relation to main pancreatic duct. *Bottom right:* Walled off pancreatic necrosis. The presence of dependent debris on the T2-weighted image allows specific diagnosis. With current imaging technology and increasing appreciation of the appearances of pancreatic cysts, specific diagnosis can be made in approximately two thirds of cases.

symptomatic.¹⁰¹ The tumor occurs more frequently in women (mean age of 57 years) and most often in the pancreatic head. The tumor contains glycogen-rich periodic acid–Schiff–positive epithelial cells delimiting cysts separated by variable amounts of fibrous septations. They most frequently occur sporadically; 60% to 80% of patients with von Hippel–Lindau syndrome will have pancreatic SCA.

SCA has two morphologic appearances: the microcystic or classic type, and the macrocystic or oligocystic type. The microcystic form, accounting for two thirds of SCAs, is a spongelike lesion formed from innumerable cysts containing clear watery fluid. The cysts range from 1 to 5 mm in the center of the mass; larger cysts (up to 2 cm) are present in the periphery. A central fibrous stellate nidus is present giving rise to radially oriented fibrous bands. This central nidus frequently calcifies. The oligocystic type has scant locules or can be unilocular. There is no central scar; the fluid may be clear but often is hemorrhagic.¹⁰² Because of the recognition of the oligocystic type of SCA, the term *microcystic serous cystadenoma* is no longer used to describe these lesions.

The imaging features of SCA reflect the morphologic appearance of the mass. The classic variety is manifested as a solitary mass that displays central calcification and a radial arrangement of dense fibrous tissue delimiting a variable number of cysts (Fig. 98-8). In some tumors, the cysts are so small and the fibrous component so dense that the lesion may actually appear “solid.”¹⁰³ As one might imagine, on MDCT, the cysts are near water density, and the surrounding fibrous network appears dense; on MRI, the appearance is dependent on the pulse sequence of the acquisition. Central calcification establishes the diagnosis of SCA, but it is present, at most, in 30% of cases,⁹⁷ best detected by MDCT. The tumors may encase vessels and

obstruct the pancreatic or biliary duct system. Nevertheless, even these seemingly aggressive tumors may remain indolent.

On T1-weighted fat-suppressed sequences, the fluid component is darker than the fibrous matrix; on T2-weighted acquisitions, the fluid component becomes more conspicuous, appearing bright because of the longer T2 relaxation time. EUS may be particularly useful in displaying the honeycombed internal structure in lesions smaller than 2 cm. EUS provides an excellent means by which to sample cyst fluid.¹⁰⁴

The oligocystic variety can be suspected when there is a unilocular nonenhancing cystic mass in the pancreatic head with a lobulated contour.¹⁰⁵ Despite the high reported specificity of this constellation of findings, differentiation of this lesion from mucinous cystic tumor or pseudocyst may be impossible.

MUCINOUS CYSTIC TUMOR

These rare neoplasms are thought to be potentially malignant; therefore, the terms *mucinous cystadenoma* and *mucinous cystadenocarcinoma* should not be used; rather, the lesion is properly referred to as mucinous cystic tumor. Mucinous cystic tumors are formed from variably atypical epithelial cells that produce mucin and are supported by an ovarian-type stroma, which does *not* communicate with the pancreatic duct system. They account for 2% to 6% of all exocrine pancreatic neoplasms.¹⁰⁶ These tumors occur almost exclusively in women, with peak incidence in the fifth decade. The female preponderance is similar to that of mucinous tumors of the hepatobiliary system, retroperitoneum, and ovary. The stromal component of the mucinous cystic tumor stains for cytokeratin markers, indicative of cellular luteinization,¹⁰² the ovarian-type stroma

Figure 98-8 Branch duct IPMN. **A.** This 1.5-cm cyst (arrow) was detected in a 49-year-old man on a CT urogram. **B.** Same patient as in **A.** This image was obtained 5 years later when the patient was seen in the emergency department with abdominal pain and hyperamylasemia. The cyst (asterisk) now measures 2.8 cm. **C.** Same patient as in **A.** MRCP obtained at same time as in **B** shows the cyst (arrow), the dilated side branch (arrowhead), and a slightly dilated main pancreatic duct. Resection revealed an intestinal-type IPMN with low- to moderate-grade dysplasia but no neoplasm.

characteristic of these lesions. It is important to remember this fact because the diagnosis of mucinous cystic tumor should probably not be considered in a male patient.

At MDCT, the lesions will display large cysts with thin septa, best seen after intravenous administration of contrast material. When calcification occurs, it is lamellated (as opposed to the starburst pattern seen in SCA) and in the periphery of the lesion (as opposed to the central location of calcification in SCA). Lesions with a higher degree of epithelial atypia will display nodules on the wall, peripheral calcification, and a more disorganized internal architecture (Fig. 98-9). Malignant lesions tend to be larger than benign lesions.¹⁰⁷ On MRI, the lesion will appear bright on T2-weighted sequences. On T1-weighted sequences, intravenous administration of gadolinium is necessary to image the septations, which become more apparent the longer the imaging sequence is carried out^{107,108} (Fig. 98-10). Mucin itself can produce decreased signal

Figure 98-9 Pancreatic mucinous cystic tumor with features of malignancy. This cyst in a 43-year-old woman has three features that must raise the suspicion that portions of the lesion will have neoplastic histologic features, including peripheral calcification, variable wall thickness (arrow), and mural nodule (arrowhead). Foci of atypia and noninvasive malignant change were confirmed at resection.

within the center of the lesion that should not be confused with the radiating septa seen in SCA. On EUS, the mural nodularity is easily recognized and can be differentiated from the honeycombed appearance of SCA. EUS is particularly valuable for aspiration of cyst fluid.¹⁰⁹ Presence of carcinoembryonic antigen in aspirated cyst fluid has a high predictive value for mucinous cystic tumor.¹¹⁰

INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM

The IPMN was first described at ERCP by Ohhashi in 1982¹¹¹; the first report in the imaging literature was by Itai and colleagues in 1986.¹¹² The entity has been reported under a wide variety of names, including ductectatic mucinous cystadenoma, villous adenoma of the main pancreatic duct, and intraductal mucinous hypersecreting neoplasm, to name a few; at this time, the term *intraductal papillary mucinous neoplasm* (IPMN) is most frequently used. The prevalence of this lesion is high among patients with pancreatic cysts. Currently, most cysts detected at imaging are assumed to be IPMN until proven otherwise.^{113,114} IPMN occurs with a slight increased frequency in male patients compared with other pancreatic cysts. The pathologic hallmarks of the lesion are diffuse or segmental dilation of the main or side branch pancreatic ducts, intraductal growth of the mucin-producing epithelial lining cells, and protrusion and dilation of the major and minor papilla with mucus excretion.¹¹⁵ In slightly more than 50% of the cases, the pancreatic duct bulges into the ampulla of Vater, with marked hypersecretion of mucus seen pouring into the duodenum at endoscopy.

Two morphologic forms are distinguished: those involving the main pancreatic duct with or without side branch involvement (Fig. 98-11), and those exclusively within the branch ducts (see Fig. 98-8). Within both of these varieties, there are five histologic types: intestinal, pancreaticobiliary, gastric, intraductal tubulopapillary, and intraductal oncocytic.¹¹⁶ Cases in which the main duct is involved have a significantly higher likelihood of harboring more malignant epithelium than those restricted to the branch ducts,^{117,118} but malignant change is not invariably found (Fig. 98-11). The different histologic types cannot be differentiated on imaging; however, the risk of malignancy varies significantly between them. Branch duct IPMNs can arise anywhere within the pancreas, although

Figure 98-10 Insulinoma. **A.** MDCT of insulinoma in a 58-year-old male patient. CT in arterial phase reveals a hyperdense mass (arrow) in the body of the pancreas. The mass appears as bright as the surrounding vessels. **B.** MRI of insulinoma in the same patient as in **A.** Arterial phase image from gadolinium-enhanced gradient recalled VIBE sequence again demonstrates the mass in the body of the pancreas (arrow). An insulin-secreting PNET was resected.

Figure 98-11 Main duct IPMN with adenocarcinoma. A. The main pancreatic duct in this 74-year-old woman is diffusely dilated (asterisk). **B.** Same patient as in **A.** A soft tissue attenuation mass is present in the pancreatic head (asterisk). Note the calcification in the more proximal portion of the main pancreatic duct (arrow). Peripheral calcifications are frequently present in these lesions.

the uncinate process, head, and neck are the most common locations. Individual lesions contain a wide spectrum of epithelial dysplasia; however, an individual lesion's biologic behavior is variable (see Fig. 98-8). Factors correlating with malignancy include advanced age, main duct involvement, concurrent diabetes or other pancreas-related abdominal symptoms, lesion size (>3 cm) and multiplicity, and presence of visible mural nodules or any other solid elements.¹¹⁹ Malignancy in main duct IPMN is more frequently encountered but not always present; patients who are symptomatic and have duct dilation of more than 8 mm are more likely to have malignant tumors than are those with less duct dilation.¹²⁰

At imaging, the lesion is characterized by increased diameter of a portion of the pancreatic duct system. Visualization is optimal with use of intravenous contrast-enhanced thin-section MDCT or T2-weighted MRI. The diagnosis is confirmed by demonstration of communication with the pancreatic duct, best determined by 3D techniques including CTCP⁴² and MRCP^{118,121} (see Fig. 98-8). Careful attention to protocol will allow the radiologist to demonstrate the bulging papilla into the duodenal lumen, a finding that when present allows distinction from chronic pancreatitis.¹¹⁹ Mural nodules or mucinous accretions can be seen on both MDCT¹²² and T2-weighted MRI¹²³ (see Fig. 98-9). EUS is particularly useful for evaluating main duct tumors, particularly the longitudinal extent of main duct involvement, aiding surgical planning.¹²⁴

A complex analytic process of the imaging findings is necessary. Despite this, considerable uncertainty about recommending additional interventions or follow-up still exists. Furthermore, the frequency and interval of the follow-up periods are not universally agreed on. First, the size of the lesion must be determined. In multiple studies, there appears to be a significant change in the risk of malignancy in tumors smaller than 3 cm (low) or larger than 3 cm.^{125,126} Current recommendations advocate aggressive characterization of lesions larger than 3 cm. Lesions smaller than 1 cm are usually observed. Uncertainty exists in deciding how to handle cysts that range between 1 and 3 cm in size. In our practice, we will attempt to characterize cysts of this size by pancreas-dedicated imaging (usually by MRI) with the explicit purpose of visualizing the cyst in relation to the main pancreatic duct. If the cyst can be characterized as an IPMN, 6-month follow-up for a 4-year period is recommended for younger patients; for asymptomatic patients with other comorbidities, the follow-up regimen is determined on a

case-by-case basis. If the cyst is uncharacterized, it is assumed to be an IPMN. EUS may be performed for larger cysts (closer to 3 cm) as opposed to 6-month follow-up for smaller cysts. Factors that influence the decisions include the age of the patient and the presence or absence of pancreas-related symptoms.¹²⁷ Regardless of the size of the cyst, we advocate cyst fluid aspiration before any cyst is resected¹²⁸; an elevated carcinoembryonic antigen level in the cyst has high predictive value for mucin content.¹²⁹

The strongest predictor of a malignant cyst is the presence of mural nodules, particularly those larger than 6 mm.¹³⁰ These may be difficult to detect on cross-sectional imaging studies; EUS is much better suited to see them. Virtually all consensus recommendations concerning pancreatic cysts agree that mural nodules are a highly significant finding in terms of risk stratification for an individual cyst. Their presence has been shown to be a more reliable independent predictor of malignancy than cyst size, septa, or mural thickness.¹³⁰

Nonoperative surveillance has become widely accepted when pancreatic cysts are initially detected. Because many will be small, the morphologic features of malignancy may not be easily recognized.¹³¹ Follow-up allows some estimate of the growth rate of an individual cyst. Branch duct IPMN that grows at a rate of more than 2 mm per year has a significantly higher rate of malignancy than that of tumor with a slower growth rate (45.6% vs 1.8%).¹³²

There are increasing numbers of case reports of metachronous development of pancreatic adenocarcinoma at sites distant to the branch duct IPMN. The incidence of metachronous tumor development is consistently reported in the range of 6% to 11%.¹³³⁻¹³⁵ This substantiates speculation that branch duct IPMN arises as a field defect in a whole pancreas that is at risk for development of malignancy. Newer molecular pathology studies have shown that metachronous tumors develop more frequently in patients with gastric-type IPMN.¹³⁶ Knowledge of molecular markers within a given lesion therefore may have significant implication in developing a follow-up schedule for an individual patient.

OTHER CYSTIC TUMORS

The solid and pseudopapillary epithelial neoplasm, also known as the Hamoudi tumor, deserves mention. This tumor is most frequently found in female patients at a mean age consistently

Figure 98-12 Solid pseudopapillary epithelial neoplasm. **A** and **B.** Images from MDCT examination in a 19-year-old woman reveal a bulky heterogeneous mass in the pancreatic tail. The higher attenuation regions reflect the solid elements within the tumor. Low-attenuation regions result from areas of prior hemorrhage. **C.** Images from MDCT examination in a 26-year-old woman. Compared with the lesion in **A** and **B**, this particular mass has a more “cystic” appearance.

reported in the mid-20s,¹³⁷ but the lesion has been reported in patients as young as 10 years and as old as 79 years. Review of the literature suggests that approximately 15% of these tumors are malignant, with the likelihood of malignancy increasing with the patient's age.¹³⁸

The proportion of solid and cystic elements within the tumor is directly related to the degree of hemorrhage the tumor has undergone. The lesion appears as a round, encapsulated mass with variable amounts of necrotic and soft tissue foci (Fig. 98-12). The presence of blood products within the tumor results in hyperintense signal on T1-weighted MR sequences.¹³⁹ No septations are visualized; central and rim calcifications have been reported in 29% of patients.¹³⁷ The recommended treatment is surgery; localized lesions are treated as low-grade neoplasms. Median survival rates of 5.2 years are reported for patients with metastatic disease.¹⁴⁰

Any pancreatic neoplasm can display a “cystic morphology.” Cystic islet cell tumor and cystic ductal adenocarcinoma have been reported. True epithelial pancreatic cysts are extremely rare in the absence of systemic cystic disease, such as adult polycystic liver and kidney disease or von Hippel–Lindau disease. When a cystic tumor of the pancreas is recognized, every effort should be made to exclude a history of acute or chronic pancreatitis because pancreatic pseudocysts remain the single most common cystic pancreatic mass.¹⁴¹

Pancreatic Neuroendocrine Tumors

Pancreatic neuroendocrine tumors (PNETs) are a heterogeneous group of tumors, some of which are associated with secretion of hormones that produce clinically recognizable syndromes. The current World Health Organization classification divides PNETs into the subcategories of well-differentiated endocrine tumor, well-differentiated endocrine carcinoma, and poorly differentiated endocrine carcinoma. The well-differentiated PNETs are further divided into those with benign behavior (confined to pancreas, nonaggressive, <2 cm in size, functional or nonfunctional) and uncertain behavior (confined

to pancreas, >2 cm in size or with angioinvasion, functional or nonfunctional). All well-differentiated PNETs are thought to be low-grade malignant neoplasms and are categorized on the basis of size, mitotic rate, cell proliferation (as measured by Ki-67 labeling index), and evidence of invasion.¹⁴²

PNETs account for 1% to 10% of all pancreatic neoplasms. Their overall prevalence is reported at 1 per 100,000, with an annual incidence of 1 to 4 cases/million persons per year. Nonfunctioning PNETs account for 14% to 30% of PNETs, although they have been reported in as high as 80%.¹⁴³ PNETs occurs with equal frequency in men and women, with peak age in the 50s and 60s. PNETs are found with equal frequency throughout the pancreas.¹⁴⁴ Increased frequency is well documented in patients with four inherited disorders: autosomal dominant multiple endocrine neoplasia (MEN 1), von Hippel–Lindau disease, tuberous sclerosis, and neurofibromatosis 1.¹⁴⁵

The most widely expected imaging appearance of PNET is a hypervascular mass best seen in the pancreatic phase of enhancement on MDCT (Fig. 98-13) or a briskly enhancing focus on fat-suppressed, gadolinium-enhanced T1-weighted MRI.^{146,147} Five percent to 10% of PNETs will be cystic; the thick enhancing peripheral rim may allow differentiation from other pancreatic cysts. On occasion, they will be manifested with an isolated duct stricture.⁸⁵

INSULINOMA

Insulinoma is the most common functioning PNET (see Fig. 98-10). Patients may present with Whipple's triad (neuromuscular disorders, hypoglycemia, and symptom reversal with administration of glucose). Fifty percent of the lesions are found in the head of the pancreas, the remainder elsewhere within the gland; 85% are solitary, and 0.5% of the lesions are extrapancreatic. Most lesions are 1 to 2 cm, and metastases occur in less than 15% of cases; however, 10% of the lesions are malignant. Malignant insulinomas are larger (measuring up to 8 cm) and produce extremely high levels of insulin or

Figure 98-13 Nonfunctioning PNET.

A. Noncontrast-enhanced MDCT. A ringlike calcification is seen in the pancreatic tail of a 48-year-old asymptomatic patient. **B.** Pancreatic phase MDCT. Same patient as in **A**. In the pancreatic phase, the low-attenuation mass is evident. Calcification in soft tissue attenuation pancreatic masses should raise the suspicion of PNET. **C.** Incidental finding in a 58-year-old patient. A cyst (asterisk) is present in the midbody of the pancreas with upstream main pancreatic duct dilation. The lesion was resected and the diagnosis of PNET confirmed. Cystic PNET is well recognized. Furthermore, specific diagnosis of the type of pancreatic cyst is not possible in all cases.

proinsulin, and metastases are present at the time of diagnosis.¹⁴⁸ When the lesion is solitary and localized, simple excision or enucleation is sufficient for treatment.

GASTRINOMA

Gastrinoma is the second most functioning PNET. Most are located in the anatomic region between the pancreatic head and common bile duct and within the first or second portion of the duodenum, the so-called gastrinoma triangle¹⁴⁹ (Fig. 98-14). The excessive gastrin production leads to the Zollinger-Ellison syndrome either as a sporadic entity or as a manifestation of MEN 1. Fifty percent to 70% of sporadic cases of Zollinger-Ellison syndrome are usually the result of tumors within the pancreas; the remaining cases are secondary to tumors located within the duodenum. Most of the gastrinomas found in MEN 1 are located within the duodenum. At diagnosis, 60% of gastrinomas already have metastasized to peripancreatic lymph nodes or, less frequently, the liver.¹⁴⁸

NONFUNCTIONING PANCREATIC NEUROENDOCRINE TUMOR

Nonfunctioning PNET has a peak incidence in the 50s and 60s with an equal distribution between men and women. The masses are usually large; 60% to 83% of lesions are malignant at the time of diagnosis, usually with liver metastases. They are frequently hypervascular at imaging. Internal calcifications are frequent; nonfunctioning PNET is the most likely etiology of a

solid-appearing pancreatic mass with dense calcifications (see Fig. 98-13). The 5-year survival rates are excellent compared with ductal carcinoma; 5-year survival rates approach 70%, and 10-year survival rates approach 50% of patients.^{150,151}

IMAGING

MDCT has been shown to increase the detection of insulinomas to 94% compared with the single-slice CT success rate of 29%.^{152,153} The median sensitivity of tumor detection for all subtypes is on the order of 84%. The overall detection rate of 85% is similar to that of MRI. MRI results reach 100% sensitivity for lesions larger than 3 cm, but MRI has extremely poor performance for smaller lesions.¹⁵⁴ On MRI, PNET displays significantly higher signal intensity than normal pancreas on T2-weighted images and will demonstrate a ringlike enhancement after intravenous administration of contrast material.¹⁵⁵ EUS and molecular methods are widely used and provide a statistically incremental improvement in the imaging assessment of these patients. Most believe that MDCT can be a first-line study, but if the findings are normal, EUS can be performed. EUS may be the better first-line test for the evaluation of suspected insulinoma.¹⁵⁶

Utility of molecular agents that target specific metabolic pathways or receptors is directly related to the specific tumor subtype. Somatostatin receptor scintigraphy is widely performed; [¹¹¹In]-pentetate (Octreoscan) is widely available for clinical use. This agent is useful only in tumors with somatostatin receptor sites. Newer agents, particularly those that

Figure 98-14 Zollinger-Ellison syndrome. **A.** MDCT scan in a 44-year-old male patient with severe upper abdominal pain. An ulcer (arrow) is present in the third portion of the duodenum. Note the mural edema. **B.** Same patient as in **A.** There is a slightly hyperdense mass (asterisk) in the groove between the undersurface of the pancreas and the medial wall of the duodenum. A well-differentiated neuroendocrine tumor (gastrinoma) was resected in this lymph node.

Figure 98-15 Metastatic disease to the pancreas. **A.** Lung cancer metastatic to the pancreas. There is a poorly defined mass with a dilated upstream main pancreatic duct. Note the bilateral adrenal masses. **B.** Melanoma metastatic to the pancreas. A hyperdense mass (arrow) is present in the pancreatic body. Without knowledge of the patient's clinical status, specific diagnosis could not be made. **C.** Ovarian cancer metastatic to the pancreas. There is a cyst in the head of the pancreas. On prior study 12 months previously, the region was normal. Differential diagnosis from any type of pancreatic cyst.

can be used with CT-PET scanning, such as 68-DOTA-NOC, display more true-positive tumor foci than [^{111}In]-DTPA octreotide.¹⁵⁷ The major utility of these and other newly developed molecular agents is increased detection of sites of unsuspected metastases.

Continuous improvements in MDCT and MRI technology also have resulted in improved detection and analysis of PNET. Using dual-energy spectral CT, Lin and coworkers¹⁵⁸ reported a 95.7% sensitivity compared with a 68.8% sensitivity with MDCT, the improvement being directly related to the ability to combine a monochromatic and iodine density image. Apparent diffusion coefficient values show an inverse correlation with Ki-67 labeling index and may help predict biologic behavior of an individual tumor.

Secondary Pancreatic Neoplasms

The pancreas can be secondarily involved by neoplasm by direct extension from a contiguous primary tumor (e.g., gastric carcinoma), invasion from local metastatic lymph nodes (e.g., invasion of the pancreatic head by metastatic peripancreatic lymph nodes draining a primary tumor of the right colon), and hematogenous metastases. Renal cell carcinoma is the most common primary neoplasm to metastasize to the pancreas. The lesions appear as hypervascular foci within the pancreatic parenchyma.¹⁵⁹ Other common sources of metastases to the pancreas include melanoma and lung cancer; however, metastases to the pancreas can be present from virtually any primary neoplasm¹⁶⁰ (Fig. 98-15).

Pancreatic Trauma

Traumatic injury to the pancreas is rare and difficult to diagnose. The retroperitoneal location of the pancreas is a mixed anatomic blessing in patients with abdominal trauma. Its fixed position anterior to the vertebral column provides excellent protection against deceleration injury and posterior stab wounds.¹⁻³ This protected environment, however, can be breached by bullets and more severe deceleration forces that may cause life-threatening pancreatic injury. Because of its rarity and nonspecific symptoms, the diagnosis of pancreatic injury is often delayed.⁴ The retroperitoneal location is detrimental to prompt diagnosis because signs and symptoms of pancreatic injury often evolve slowly and may be misleading.⁵ Delay in diagnosis and initiation of treatment in large part contributes to the potentially significant complications of pancreatic injury, including pseudocyst, abscess and fistula formation, sepsis, and chronic pancreatitis.⁶ There is considerable truth to the surgical aphorism that “the pancreas is not your friend” in terms of the unforgiving nature of pancreatic injuries.^{1,7} Because of the retroperitoneal location of the pancreas, pancreatic injuries are not easily diagnosed by diagnostic peritoneal lavage, which has a high false-negative rate. Furthermore, the classic presentation of upper abdominal pain, leukocytosis, and hyperamylasemia common in acute pancreatitis is far less reliable in the setting of pancreatic trauma.^{4,8,9} Multidetector computed tomography (MDCT), ultrasound, magnetic resonance imaging (MRI) with magnetic resonance cholangiopancreatography (MRCP), and endoscopic retrograde cholangiopancreatography (ERCP) can expedite the diagnosis and management of these patients.¹⁰

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Pancreatic injuries are relatively rare, found in only 72 (0.4%) of more than 16,000 trauma patients.¹¹ The pancreas is involved in only 2% of penetrating injuries and 5% to 12% of blunt abdominal injuries. The incidence of pancreatic trauma is increasing, however, because of the rising number of high-speed automobile injuries and gunshot wounds. Approximately three quarters of pancreatic injuries are due to penetrating trauma caused by gunshot or stab wounds. The remainder are secondary to blunt trauma caused by a sudden localized force to the upper abdomen as a result of a direct blow from a fall, a kick, or a steering wheel or bicycle handlebar injury. These forces compress the neck or body of the pancreas against the spine just to the left of the mesenteric vessels, causing crushing injury or transection.^{3,12} Blows to the left of midline may injure the pancreatic tail or distal body and may be associated with concurrent splenic, gastric, left renal, or descending colonic injury.⁹ Blows to the right of midline may injure the pancreatic head or uncinate process along with the bile ducts and may be associated with additional hepatic, duodenal, right renal, or ascending colonic injury.⁹

Although pancreatic injuries are relatively infrequent, they have an overall mortality rate of 16% to 20%, which increases substantially when they are associated with other abdominal injuries.^{3,11,13} The mortality rate is independent of the mechanism or grade of injury.¹¹ The mortality rates vary on the basis of the location of pancreatic injury, with rates of 22%, 18%, and 10% for the head, body, and tail, respectively.¹⁴ Approximately 90% of patients with pancreatic damage have concomitant visceral injuries because of the intimate relationship between the pancreas and the duodenum, biliary tract, colon, spleen, stomach, and major systemic and splanchnic blood vessels.¹⁵ Indeed, there are an average of 3.5 associated intra-abdominal injuries in patients with pancreatic trauma.³ In patients with combined pancreatic and duodenal injuries, the mortality rates are 5% for stab wounds, 15% for blunt injuries, 20% for gunshot wounds, and more than 50% for shotgun wounds.¹⁶ Most of the deaths occur within the first 48 hours of injury and are due to hypovolemic shock and major hemorrhage that result from vascular injury. The main source of delayed morbidity and mortality is disruption of the pancreatic duct, as isolated pancreatic injuries that spare the pancreatic duct rarely result in a poor outcome.⁸ Multiple organ failure and infection account for the remaining deaths. One third of survivors have major complications, such as chronic pancreatitis, pancreatic fistula, pseudocyst, pancreatic abscess, delayed massive hemorrhage, focal necrosis, hypocalcemic tetany, diabetes, and steatorrhea.¹⁷ Fistula formation after pancreatic trauma is seen in 7% to 20%.^{18,19} A delay in diagnosis is a major contributing factor to the high morbidity and mortality associated with pancreatic

injury. Although the need for surgical exploration is obvious in patients with penetrating trauma, pancreatic injury may be clinically occult, and a high index of suspicion must be maintained.^{17,20} With the current emphasis on nonoperative management of blunt trauma with established solid organ injuries, the risk of missed pancreatic injury becomes even more important.⁴

Rarely, the pancreas is injured during CT- or ultrasound-guided pancreatic biopsy, leading to pancreatitis or major hemorrhage.^{21,22} Even more uncommon is the possibility of pancreatic injury during laparoscopic urologic surgery, with an incidence of 0.44%, exclusively reported in left-sided procedures.²³

CLINICAL FINDINGS

The classic clinical triad of acute pancreatic trauma of upper abdominal pain, leukocytosis, and hyperamylasemia is of limited value in the diagnosis of pancreatic injury. The serum amylase level is often elevated in patients with pancreatic trauma, but it may initially be normal in a large percentage of patients, especially if it is obtained within 3 hours of trauma.^{7,24,25} Elevated serum amylase and lipase levels may be seen in only 73% to 82% of cases, respectively.⁸ Hyperamylasemia is a non-specific finding and can be seen with bowel injuries and salivary gland contusion from head injuries. The degree of serum hyperamylasemia does not correlate with the severity of pancreatic injury and may actually be greater in patients with contusions than in those with frank transections.^{7,26} The retroperitoneal location of the pancreas often masks symptoms of significant injury. In some cases, the patient may be asymptomatic initially, with pain, tenderness, and abdominal distention developing gradually in a 12- to 24-hour period. Peritoneal lavage results are usually negative if the peritoneum overlying the pancreas remains intact.^{5,7} Another clinical sign recently shown to correlate with the presence of pancreatic injury in children is the “seat belt sign.” Pancreatic injury was 22 times more commonly present in children with this sign (erythema, ecchymoses, and abrasions across the patient’s abdominal wall resulting from the vehicle’s seat belt restraint).²⁷

SURGICAL CLASSIFICATION

Box 99-1 details the classification system proposed by the American Association for the Surgery of Trauma that describes

pancreatic injuries.^{9,28,29} This remains the most recent classification system and is still in use. It addresses key issues that are of importance to both the surgeon and the radiologist: the depth and location of the pancreatic injury, the degree of parenchymal disruption, and the integrity of the ampulla and main pancreatic duct. It acknowledges the significance of more complex injuries to the pancreas, particularly injuries that affect the pancreatic duct and the head of the gland; it also allows correlation with other organ injury scales.²⁸

RADIOLOGIC FINDINGS

Computed Tomography

CT is the preferred means of evaluating patients with blunt abdominal trauma.^{4,10,30-36} Pancreatic lacerations are often subtle relative to injuries involving the liver, spleen, or kidneys and difficult to visualize on imaging studies immediately after trauma. With continued improvements in MDCT technology, near-isotropic CT data sets with three-dimensional postprocessing techniques may improve detection and characterization of pancreatic lacerations. Focal pancreatic enlargement and peripancreatic fluid are suggestive of pancreatic injury, and faint lacerations or fracture lines may be seen on closer inspection¹⁰ (Figs. 99-1 and 99-2). The radiologist must rely on secondary findings because many injuries are manifested as pancreatitis with diffuse or focal swelling of the pancreas.^{10,30,31} Minor thickening of the anterior limb of Gerota’s fascia and fluid or increased attenuation in the anterior pararenal space, small bowel mesentery, or transverse mesocolon may be the only CT abnormalities.³² Fluid between the pancreas and the splenic vein was initially thought to be a useful sign of pancreatic injury.³³ This sign was subsequently found to be neither sensitive nor specific in a later study.³⁴ Fluid in this location, however, should direct the radiologist to a closer examination of the pancreas.^{10,29} A list of CT findings suggestive of pancreatic injury is shown in Box 99-2.^{9,10}

A major limitation of CT in pancreatic injury is that it often cannot reliably assess the integrity of the pancreatic duct. Several postprocessing techniques, including curved planar

BOX 99-1 THE AMERICAN ASSOCIATION FOR THE SURGERY OF TRAUMA PANCREATIC INJURY GRADING SCALE

Grade	Injury Description
I Hematoma	Minor contusion without ductal injury
Laceration	Superficial laceration without ductal injury
II Hematoma	Major contusion without ductal injury or tissue loss
Laceration	Major laceration without ductal injury or tissue loss
III Laceration	Distal transection or pancreatic parenchymal injury with ductal injury
IV Laceration	Proximal transection or pancreatic parenchymal injury involving the ampulla
V Laceration	Massive disruption of the pancreatic head

Figure 99-1 CT findings in pancreatic contusion. Axial MDCT scan of a 44-year-old woman involved in a motor vehicle accident shows a contusion of the pancreatic head (short arrow) and a subtle laceration of the head of the pancreas (long arrow). Note the presence of fluid outlining the duodenum and portion of the pancreatic head (arrowheads).

Figure 99-2 CT of superficial pancreatic laceration. CT scan of a 27-year-old patient with a stab wound to the abdomen shows a laceration through the hepatic parenchyma (curved arrow), with concomitant superficial laceration of the pancreatic head (long arrow). A small amount of fluid is seen between the pancreas and liver (short arrow). Subsequent endoscopic retrograde pancreatogram was negative.

BOX 99-2 FINDINGS SUGGESTIVE OF PANCREATIC INJURY ON COMPUTED TOMOGRAPHY

- Pancreatic laceration or fracture
- Focal (or diffuse) pancreatic enlargement
- Pancreatic contusion or hematoma
- Areas of diminished or heterogeneous enhancement
- Fluid between the splenic vein and pancreas
- Fluid in the peripancreatic fat, mesocolon, and mesentery
- Peripancreatic or mesenteric fat stranding
- Fluid in the anterior and posterior pararenal spaces or lesser sac
- Thickening of the left anterior pararenal fascia
- Dilation or discontinuity of the pancreatic duct
- Peripancreatic fluid collections, including pseudocyst formation
- Abscess or fistula formation
- Injuries to adjacent structures, including the duodenum, liver, and spleen

reformats and minimum intensity projection images, that are now feasible with isotropic or near-isotropic data sets have resulted in improvements in the visualization of the pancreatic duct by MDCT, but they still require validation in the trauma setting. As CT still may not directly show the pancreatic duct injury, such injury may be suspected on the basis of the degree of parenchymal injury.¹⁰ In addition, the pancreas may appear relatively normal on initial examinations. It has been reported that in 20% to 40% of patients with acute blunt pancreatic trauma, the pancreas can appear normal, especially within 12 hours after the injury.

Later examinations may demonstrate injuries not seen on the initial examination; however, this may relate to the characteristic evolution of pancreatic injury rather than an inaccurate initial examination. The tear progressively increases in size and becomes more well defined, often associated with extrapancreatic fluid collections.³⁷⁻⁴¹ Repeated scanning in 12 to 24 hours can be helpful if there is a strong suspicion for fracture in the face of a negative CT result.⁴² Some of the prior reports of poor

Figure 99-3 Pancreatic lacerations and multiorgan injury. A 16-month-old toddler was involved in a minivan accident. Contrast-enhanced CT demonstrates multiple pancreatic lacerations (black arrowheads), devitalized spleen (white arrow), a vascular injury of an ectopic unfused kidney (curved white arrow), right hepatic laceration (open black arrows), and subcutaneous emphysema (open white arrow) from a pneumothorax. The patient also had a spinal compression fracture. (Courtesy Andrew J. Fisher, MD, Mallinckrodt Institute of Radiology, St. Louis, Mo.)

results with CT examination may in part relate to the studies being performed without helical or MDCT scanners, thin slices, and optimal intravenous contrast material or with lack of oral contrast material.²⁶ Sensitivity and specificity of CT in pancreatic injury have improved with the use of MDCT and thinner collimation.⁴³

MDCT findings of pancreatic duct injury are either highly sensitive and nonspecific or insensitive and specific. For example, in a study aimed at evaluation of blunt pancreatic trauma with MDCT, it was determined that the finding of low-attenuation peripancreatic fluid was 100% sensitive and only 4.9% specific. Alternatively, identification of pancreatic laceration involving more than 50% of the parenchymal width had a sensitivity of 50% and a specificity of 95.1%.

Pancreatic contusions most often are isodense but occasionally may present as hyperdense masses because of intraparenchymal hemorrhage or may be hypodense due to edema (Fig. 99-1). A laceration through the pancreas is usually manifested by a thin linear lucency (Fig. 99-2). Pancreatic fractures may be seen as well-demarcated lucent defects traversing the gland, generally involving the neck of the pancreas perpendicular to its long axis (Figs. 99-3 and 99-4). There is often little or no separation of the pancreatic fragments, and the density change can be subtle but may be obscured by surrounding hematomas and fluid collections or streak artifacts.⁴⁴ Dynamic scanning after bolus injection of contrast medium is important in fracture detection because it improves visualization of normal enhancing pancreatic parenchyma.^{31,32} Pseudocysts may form within a few days after pancreatic duct laceration and appear similar on CT to pseudocysts from pancreatitis (Fig. 99-5).

Ultrasound

Although ultrasound is sensitive to demonstrate intra-abdominal fluid (hemoperitoneum), it has limited value to demonstrate pancreatic injuries.⁴⁵ Ultrasound in pancreatic injury can miss associated hemorrhage because of the retroperitoneal location of the pancreas. The actual pancreatic parenchymal injury may be difficult to visualize sonographically. In addition, many of these patients have an associated ileus, limiting sonographic evaluation of the pancreas. The sonographic findings may be relatively subtle, usually demonstrating nonspecific gland enlargement caused by pancreatitis or contusion.⁴⁵⁻⁴⁸ The sensitivity of conventional ultrasound in the diagnosis of pancreatic trauma is reported to be low (45.7%-63%).

Even with these limitations, ultrasound is usually the first-choice screening test in the pediatric patient. Contrast-enhanced ultrasound is an imaging modality that has shown promise for the assessment of hepatic, splenic, and renal trauma. Although little research has focused on contrast-enhanced evaluation for

Figure 99-4 CT findings in pancreatic transection. CT scan of a pediatric patient, victim of child abuse, shows a large, well-demarcated lucent defect representing a pancreatic fracture with transection of the pancreas (arrows). (Courtesy Christine Menias, Mallinckrodt Institute of Radiology, St. Louis, Mo.)

pancreatic trauma, there are a few animal-based studies that show promise. Similar to conventional ultrasonography, the portability and cheaper cost are major benefits.

Magnetic Resonance Pancreatography

MR pancreatography (MRCP) has recently been established as a superb alternative for direct imaging of the pancreatic duct.^{49,50} Advantages of MRCP over ERCP include its noninvasiveness, decreased cost, and wider availability. Furthermore, MRCP allows assessment of the whole pancreatic anatomy, including not only the pancreatic duct but also the parenchyma. In addition, this imaging modality allows assessment of any peripancreatic collections and of the pancreatic duct beyond a site of disruption^{10,51} (Fig. 99-5). MRCP may also reveal ductal abnormalities, such as pancreas divisum, important information for the endoscopist to know before ERCP.¹⁰ MRI has been shown to accurately detect disruption of the pancreatic duct.

Newer refinements and technical advances in MRCP, including secretin-enhanced MRCP, provide additional information. Dynamic assessment improves detection of pancreatic ductal anatomy and presence of leak after trauma.

Pancreatic injuries rarely occur in isolation, and MRI also allows assessment of additional organs in the upper abdomen, including the liver, kidneys, and spleen.

The exact role of MRCP in the setting of acute pancreatic injury has not yet been established. Controversy exists about its usefulness as a screening tool in the acute setting. As MRI becomes more widely available and technology continues to improve, more studies and clinical experience are needed to establish the exact role of MRCP in acute pancreatic injury.

Conventional Pancreatography

The main pancreatic duct is a rigid and brittle structure compared with the pancreatic parenchyma. Accordingly, the duct may be lacerated without producing cross-sectional imaging abnormalities or surgically detectable peripancreatic hemorrhage or capsular disruption. The diagnosis can be missed at the time of surgical exploration, and this has led some surgeons to advocate routine intraoperative or preoperative pancreatography to avoid the morbidity and mortality of an unsuspected or a misdiagnosed ductal disruption.⁵²⁻⁵⁷ ERCP is not an appropriate screening test for pancreatic trauma; furthermore, the role of MRCP in this setting has not yet been firmly established.

Figure 99-5 Pancreatic duct injury and subsequent pseudocyst formation. The initial CT scan showed no abnormality in the pancreas, but the patient returned with severe abdominal pain. **A.** Thick-slab rapid acquisition and relaxation enhancement (RARE) MRCP image shows the disrupted duct (short arrow) and the resulting peripancreatic fluid collection (long arrow). Note how it is feasible with MRCP to evaluate the pancreatic duct distal to the site of injury and extravasation (curved arrow). **B.** Short-term follow-up axial MDCT scan shows a more organized pancreatic pseudocyst (arrow), which was subsequently successfully drained.

However, in cases in which the CT scan or MRCP study is equivocal or technically inadequate, emergent ERCP is useful in identifying the presence and location of pancreatic duct disruption. Demonstration of a normal duct can obviate the need for exploratory surgery in these patients. The technique is not universally available, especially on an emergent basis. In addition, patients must be clinically stable for the examination. The ductal transection appears as either duct obstruction or extravasation of contrast material from the pancreatic duct. ERCP is also useful in detecting post-traumatic pancreatic ductal strictures and pseudocyst communication.⁵³⁻⁵⁷

Gastrointestinal Studies

Pancreatic trauma is often associated with duodenal injury. When coexisting pancreatic and duodenal injuries are suspected, water-soluble agents can disclose duodenal perforation or mass effect involving the duodenum from acute pancreatitis or pseudocysts.⁵⁸

TREATMENT

The first priority in pancreatic trauma is to control hemorrhage and to contain bacterial contamination. The other main management priority is the identification of specific pancreatic injury with special attention to the integrity of the ductal system. Ductal injury is the single most important factor in late morbidity and mortality. Most pancreatic injuries can be managed with closed external drainage.⁹ Débridement of devitalized pancreatic tissue adjacent to the fracture site is essential in severe pancreatic injuries. It is important, however, to preserve at least 20% to 50% of functional pancreatic tissue whenever possible. Resection should be accompanied by drainage and duodenal diversion for concurrent pancreatic head and duodenal injuries. If there is only a contusion or laceration without evidence of major duct disruption, suture closure and external drainage usually suffice. Severe injuries of the pancreatic head can be managed according to their appearance on intraoperative pancreatography. If the duct is intact, wide-bore drainage should suffice. If duct injury is demonstrated, a Roux-en-Y diversion may be considered.⁵⁹ However, increased complication rates of up to 60% have been reported in patients with high-grade injuries treated with pancreaticojejunostomy, suggesting that distal pancreatectomy, when feasible, is a superior operative treatment for these patients.⁶⁰

Controversy exists about the optimal management of grade III injury of the left pancreas. Drainage alone was effective in 54 of 63 patients with gunshot wounds, with low mortality, but many complications were seen, generally related to the large number of associated organ injuries.⁶¹ Another group performed distal pancreatectomy and splenectomy in 48 of 57 patients with gunshot wounds to the left aspect of the pancreas, also with a low mortality rate but many complications due to associated organ injury.⁶² Patients who had distal pancreatectomy with splenic preservation had a significantly lower complication rate (22% vs 73%); however, this is probably due to increased comorbidities, such as associated visceral or splenic injury and the emergent nature of the surgery.⁶⁰ The decision about whether to salvage all or part of the spleen is based on both patient hemodynamics and age. Again, overlooked or underestimated pancreatic injury can lead to potentially disastrous complications.²⁶ Pancreatic abscesses may develop owing

to inadequately drained fluid collections that become infected from intestinal spillage or bacteremia.³⁷

Endoscopic pancreatic duct stent placement has been described in the literature, with good results.^{6,60,63} Case reports have described good short-term results and a potential role in the delayed management of traumatic pancreatic duct disruption with endoscopic pancreatic duct stenting.⁶ Successful outcomes with pancreatic duct stenting were described in partially disrupted ducts with placement of a bridging stent.⁶³ However, whereas good short-term results have been reported with duct stenting, later complications, including stricture formation, inability to subsequently remove the stent, and stent migration, raise questions about the utility of this procedure in the acute phase.⁶⁰ More important, pancreatic duct stenting in the acute phase may delay timely operative intervention and definitive repair of life-threatening injuries. Therefore, it has been proposed that pancreatic duct stenting be used later to treat post-traumatic pancreatic fistulas.⁶⁰

The optimal management of pancreatic injuries in children has remained controversial. Similar to nonoperative management of splenic and hepatic injuries, there has been a trend toward nonoperative management of pancreatic injuries in children without major ductal injuries or clinical deterioration.^{64,65} ERCP has been advocated for management of these children; demonstration of a transected pancreatic duct typically requires exploratory laparotomy with a spleen-preserving distal pancreatectomy.⁶⁶ There is limited experience of endoscopic treatment with stent placement in the pediatric population. In a small series of nine children with main duct injury treated by an endoscopically placed stent, all children managed with therapeutic ERCP avoided pancreatic resection, although most (66%) developed pancreatic fluid collections requiring drainage.

Pancreatic Surgery

INDICATIONS FOR PANCREATIC SURGERY

Benign Disease

Most attacks of acute pancreatitis are self-limited and respond to conservative management not requiring any radiologic imaging or management.⁶⁷ The role of surgery during an episode of acute pancreatitis is limited to débridement of infected necrotic tissue, drainage of abscesses that cannot be satisfactorily drained percutaneously, and control of massive hemorrhage from ruptured vessels or pseudoaneurysms.⁶⁸ Infected pancreatic necrosis, pancreatic abscess, severe hemorrhagic pancreatitis, and pseudoaneurysm formation are the few remaining indications for open surgery in acute pancreatitis. Even when it is indicated, surgery is frequently delayed or even replaced by minimally invasive surgical techniques.⁶⁹ Simple abscesses and acute pseudocysts can be drained percutaneously with use of CT for diagnosis and CT or sonographic guidance during percutaneous catheter management.^{70,71} Sterile necrosis is managed nonsurgically.^{72,73} The term *walled-off pancreatic necrosis* was introduced to describe the evolution of a postnecrotic pancreatic fluid collection by the 2007 revision of the Atlanta classifications. In walled-off pancreatic necrosis, a thick wall develops without an epithelial lining, mimicking a pseudocyst; however, it can be differentiated on CT images by the presence of internal debris (typically fat in attenuation), larger size, extension to paracolic space, irregular wall definition, and

pancreatic deformity or discontinuity. It can be treated conservatively if it is sterile. However, infected or symptomatic collections are usually treated with direct endoscopic necrosectomy, conventional transmural endoscopic drainage, or percutaneous drainage. Overall, more than 90% of patients with sterile necrosis can be successfully treated without surgical intervention.⁷⁴⁻⁷⁶ Persistent sepsis caused by infected, necrotic pancreatic tissue requires surgical drainage and débridement because the necrotic tissue cannot be removed by percutaneous drainage. Differentiation between sterile and infected necrosis is possible by CT- or ultrasound-guided aspiration of necrotic foci.^{72,73}

Severe hemorrhagic pancreatitis or hemorrhage from pseudoaneurysm formation also requires prompt intervention. Operative débridement of the necrotic tissue and aneurysm repair can be more safely and effectively accomplished if they are preceded by preoperative angiographic identification and embolization.^{77,78} With embolization, conservative therapy may be attempted instead of surgery. Some surgeons advocate emergent cholecystectomy and common duct exploration in patients with presumed gallstone pancreatitis in the hope that removal of the offending stones will ameliorate the severity of pancreatitis.⁷⁹⁻⁸¹ Most surgeons prefer to wait until the acute episode of pancreatitis resolves because of the high operative mortality associated with early aggressive intervention.⁸⁰ The role of early endoscopic removal of stones by ERCP is generally accepted in acute biliary pancreatitis with biliary obstruction or cholangitis but is still controversial in cases lacking such clear findings.^{72,73,82-85} One study recommended that MRCP be used as an initial diagnostic tool; if stones are visualized in the common bile duct, urgent ERCP is recommended. Conversely, if there are no common bile duct stones, the patient can be spared the invasive ERCP.⁸⁶ Most cases of gallstone pancreatitis resolve without complication.

The management of patients with chronic pancreatitis remains a challenging problem. Main indications for surgery remain intractable pain, suspicion of malignant disease, and involvement of adjacent organs. Less frequent indications for operative treatment include complications such as pseudocysts, nonresolving biliary or duodenal obstruction, internal pancreatic fistulas, and left-sided portal hypertension resulting from splenic vein thrombosis. The surgical approach usually involves proximal pancreatic resection, but lateral pancreaticojejunal drainage may be used for large-duct disease. The duodenum-preserving head resections of Beger and Frey provide overall good pain control and preservation of pancreatic function. Thoracoscopic splanchnicectomy and the endoscopic approach await trials to confirm their efficiency in the management of chronic pancreatitis. Newer advances in endoscopic management, including the use of fully covered self-expandable metal stents, have been recently explored in chronic pancreatitis-related biliary duct strictures for which conventional treatment with plastic stents has failed. Furthermore, endoscopic ultrasound-guided transmural drainage of the main pancreatic duct with a duct-gastrostomy has been introduced as a newer alternative treatment option in selected cases. Further studies are needed to validate these techniques.

Common bile duct obstruction is surgically addressed by distal Roux-en-Y choledochojejunostomy; but in combination with duodenal obstruction, it must be treated by pancreatic head resection. Pancreatic ascites due to disrupted pancreatic duct should be treated by internal drainage.⁸⁷⁻⁹⁴ Obstruction of

the pancreatic or bile duct by a stricture, calculus, or series of strictures is a major cause of pain. Ductal drainage procedures often result in pain relief and improved pancreatic function.⁹⁵⁻¹⁰² If there is no ductal dilation, decompressive procedures usually will not ameliorate the patient's pain. Nerve ablation (celiac nerve block) has been advocated before consideration of extirpative procedures because these operations are associated with exocrine and endocrine pancreatic insufficiency.¹⁰³⁻¹⁰⁵

Acute and chronic pseudocysts can be managed surgically, but radiographically guided or endoscopic management should be attempted first.¹⁰⁶⁻¹¹³

Malignant Disease

Surgical management of ductal adenocarcinoma of the pancreas was previously considered to be controversial.¹¹⁴⁻¹²⁰ Most controversies, however, such as whether to perform extended lymph node dissection and standard versus pylorus-preserving resections, have been addressed by randomized, prospective clinical trials.^{121,122} From a surgical perspective, the first objective in the management of pancreatic carcinoma is to determine the potential for resection.¹²² Factors contraindicating resection include the presence of distant metastases; major venous thrombosis; and superior mesenteric, celiac, or hepatic artery encasement.¹²¹ Pancreatoduodenectomy (the Whipple procedure) is the only proved cure for carcinoma of the pancreatic head. Unfortunately, success is modest, with an overall 5-year survival rate between 15% and 25% in patients who have undergone resection.¹²³ The Whipple procedure is one of the most complex of all surgical procedures, with significant associated morbidity and mortality. A better technical success rate and fewer overall complications have been described in high-volume regional referral centers that perform many such surgeries.¹²² Surgery is effective in palliating certain symptoms: relief of jaundice with biliary-enteric bypass; relief of duodenal obstruction with gastrojejunostomy; and relief of pain by chemical splanchnicectomy.¹¹⁷ Biliary bypass and celiac nerve block can be performed percutaneously.

The management of pancreatic cystic neoplasms depends on the presence of symptoms, malignant potential of the lesion, and surgical risk. Serous cystadenomas do not require resection unless the patient is symptomatic or the diagnosis is uncertain. In contrast, mucinous cystic neoplasms should be resected because of their higher malignant potential.^{124,125} When these lesions are aspirated preoperatively, in addition to the presence of malignant cells, the cystic fluid carcinoembryonic antigen level has been shown to accurately predict the presence of a mucinous neoplasm.¹²⁶ Cystic neoplasms of the pancreas have a much better prognosis than ductal adenocarcinomas. In fact, nearly half of patients with cystadenocarcinomas can be cured by surgical therapy.^{127,128}

The results of surgical intervention are similarly encouraging with pancreatic neuroendocrine tumors. Insulinomas are the most frequent functional neuroendocrine tumors and are characterized by inappropriately high levels of insulin. They are typically small and multiple in 10% to 15% of patients. Preoperative angiography, MRI, and CT and intraoperative ultrasound reduce the need for "blind" pancreatic resection when the tumor is not palpable.¹²⁹⁻¹³¹ The management of gastrinomas is more complicated due to the advent of more effective medical therapy that reduces the complications of peptic ulcer disease. Excision of gastrinomas is still recommended because of the lower rate of hepatic metastasis in

surgically treated patients.¹³² Furthermore, more than 60% of gastrinomas are malignant, and more than half have metastasized by the time of operation. As many as 75% of patients have multiple lesions, and many of these tumors cannot be localized by preoperative studies or by surgical palpation. The preferred course for these tumors is surgical exploration in all good-risk patients. If the disease appears localized, primary surgical excision is undertaken.¹¹⁸ Proton pump inhibitors are indicated in patients with unresectable lesions, rendering gastrectomy unnecessary.¹³³

ROLE OF RADIOLOGY

In patients with pancreatic neoplasms, the radiologist should provide the surgeon with information concerning the extent of the tumor and the presence of local or distant tumor spread. Because surgery for pancreatic carcinoma is extensive with significant associated morbidity, patient selection is extremely important so that a patient who is a candidate for potentially curative surgery is not excluded while at the same time someone is not subjected to an unnecessary operation. The goal of staging through imaging, therefore, is to distinguish resectable from unresectable disease.

The extent of testing necessary to determine resectability has historically been controversial in the surgical literature but is becoming less so with the advent of the high-quality imaging abilities of MDCT and MRI. Advocates of limited preoperative evaluation followed by surgical exploration in all patients with nonmetastatic pancreatic tumors believe that intraoperative evaluation is the most sensitive method of determining resectability. They suggest that if the tumor is found to be unresectable, operative palliation is the best way to provide sustained relief of symptomatic jaundice or gastric outlet obstruction.^{134,135} Others argue that direct intraoperative assessment of the extent of retroperitoneal tumor growth in relation to the superior mesenteric artery origin is not completed until the final step in tumor transection, after gastric and pancreatic transection, when the surgeon is committed to resection even if all of the tumor cannot be safely removed.¹³⁶ The need for accurate preoperative assessment is substantiated by the large number of positive-margin resections reported and the high incidence of local recurrence after resection.^{137,138} Other series suggest that for most patients with unresectable disease, laparotomy for palliation may be avoided owing to the advances in endoscopic, percutaneous, and laparoscopic methods of biliary decompression.¹³⁹

In pancreatitis, imaging has two major roles: staging of the severity of the inflammatory process and detection of complications, such as fluid exudation, vascular compromise, pancreatic necrosis, pancreatic abscess, and pseudocyst formation.

Computed Tomography

With MDCT, it is now possible to attain better spatial resolution along the z-axis as well as to further improve temporal resolution. MDCT permits rapid thin-section acquisition of regional body anatomy with multipass multiplanar data obtained during defined circulatory phases to best outline the vasculature and to detect and characterize focal parenchymal lesions. Typical imaging protocols include multiphasic imaging with unenhanced pancreatic parenchymal phase and venous phase imaging.¹⁴⁰⁻¹⁴³ The detection and characterization of benign or malignant pancreatic tumors and imaging of inflammatory

pancreatic disease with its associated complications can be successfully performed by MDCT.^{140,144}

The extent and severity of pancreatitis can be assessed by evaluating the degree of pancreatic enlargement in addition to the number, size, and location of pseudocysts and peripancreatic fluid collections and the presence of pancreatic necrosis. Associated complications include vascular thrombosis and gastrointestinal fistula formation. In patients with acute pancreatitis, a double-pass helical imaging technique that includes pancreatic and hepatic phase acquisitions is potentially beneficial for outlining focal areas of pancreatic necrosis.^{145,146}

In up to 30% of patients with definite clinical and laboratory signs of acute pancreatitis, the pancreas may appear completely normal on CT. Similarly, in 10% of patients with clinically diagnosed chronic pancreatitis, there are no abnormalities seen on CT.^{144,147}

MDCT currently plays a vital role in pancreatic cancer staging as imaging before surgery most often determines whether the surgery is performed. CT is often considered to be the optimal imaging modality for pancreatic cancer staging. Continued advancements in computers, scanner technology, and three-dimensional software have improved CT detection of smaller masses and staging by greatly improving the visualization of the pancreas and adjacent vasculature. Another potential advantage is anecdotal evidence that the ability to obtain thinner slices can improve detection of small peritoneal metastases.^{140-143,148}

The major finding shown by MDCT is a hypoattenuating pancreatic mass on early arterial (pancreatic) phase imaging, with associated pancreatic duct dilation. In tumors located in the pancreatic head, biliary duct dilation is expected. An important feature for determining potential tumor resectability is perivascular tumor invasion, particularly in relation to the celiac and mesenteric arteries, the splenic and superior mesenteric veins, and the portal confluence.¹⁴⁵ Curved multiplanar reformatted images and high-quality, volume rendered, three-dimensional reconstructions may help depict excellent vascular detail. Invasion of the root of the mesentery and transverse mesocolon associated with ascites is an ominous finding that suggests peritoneal carcinomatosis. Local extrapancreatic extension on CT is suggested by contiguous organ involvement except for the duodenum, which is included in the resection in a Whipple procedure. CT signs suggesting that the lesion is unresectable include hepatic, omental, or peritoneal metastases; locally advanced extension into the peripancreatic and retroperitoneal soft tissues; thrombosis of the portal vein–superior mesenteric vein confluence; and encasement of the celiac trunk or superior mesenteric artery.¹⁴⁹⁻¹⁵⁵ Vascular invasion, lymph node metastasis, liver metastasis, and peritoneal carcinomatosis are generally accepted reasons for unresectability.¹⁵⁶⁻¹⁵⁸ Positive predictive values of CT for surgical unresectability have been excellent, ranging from 89% to 95%.¹⁵⁹⁻¹⁶¹ Among patients with tumors judged potentially resectable on the basis of CT criteria, however, surgical results show that 60% to 91% of the tumors are truly resectable. The most frequent reasons for tumor unresectability found at surgery are small (<1 cm) hepatic, peritoneal, or omental metastases, lymph node metastases, and vascular invasion.^{122,144,158,160,162-164}

If a CT examination considers a tumor resectable, this should be considered potential resectability because CT can miss subtle spread of disease. Literature, including a study by Vargas and associates,¹⁶⁵ reported an accuracy of 99% and a negative

predictive value of 100% for prediction of vascular invasion by tumor with MDCT. Various grading systems for vascular involvement have been described; some suggest that different criteria may be necessary in evaluating arteries and veins. Vascular involvement is confirmed by the presence of tumor thrombus or vascular occlusion (nonvisualization, vessel cutoff, or abrupt changes in vessel caliber).^{144,166,167} Nonetheless, other adjunct studies, including endoscopic ultrasound and staging laparoscopy, may provide additional information before major pancreatic surgery is undertaken. CT is also important in the evaluation of other solid pancreatic neoplasms. A major advantage of multiple phase postcontrast CT in patients with islet cell or carcinoid tumors is the detection and localization of hypervascular metastases. Islet cell tumors and metastases are most typically hypervascular. If tumor ablation therapy is being considered, MDCT is important in the pretreatment planning.¹⁴⁵ CT and MRI are also effective in the evaluation of cystic tumors of the pancreas, including serous and mucinous tumors, as well as intraductal papillary mucinous neoplasms.

In summary, the importance of CT in pancreatic imaging has been further enhanced by the advent of MDCT technology, which is highly reliable in assessing pancreatitis and staging pancreatic neoplasms. It has become the “gold standard” in the work-up and continued surveillance for the majority of these patients.

FDG PET/CT
